ABSTRACT

We characterize the Spitzer Wide-area Infrared Extragalactic Legacy Survey (SWIRE) galaxy populations in the SWIRE validation field within the Lockman Hole, based on the 3.6–24 μm Spitzer data and deep U, g′, r′, i′ optical imaging within an area ∼1/3 deg² for ∼16,000 Spitzer SWIRE sources. The entire SWIRE survey will discover over 2.3 million galaxies at 3.6 μm and almost 350,000 at 24 μm; ∼70,000 of these will be five-band 3.6–24 μm detections. The colors cover a broad range, generally well represented by redshifted spectral energy distributions of known galaxy populations; however, significant samples of unusually blue objects in the [3.6]−[4.5] color are found, as well as many objects very red in the 3.6–24 μm mid-IR. Nine of these are investigated and are interpreted as star-forming systems, starbursts, and active galactic nuclei (AGNs) from z = 0.37 to 2.8, with luminosities from L_IR = 10^{10.3} to 10^{13.7} L_☉.

Subject headings: galaxies: evolution — infrared: galaxies

1. INTRODUCTION AND OBSERVATIONS

The Spitzer Wide-area Infrared Extragalactic Legacy Survey (SWIRE; Lonsdale et al. 2003), will map the evolution of spheroids, disks, starbursts, and active galactic nuclei (AGNs) to z > 2, within volumes large enough to sample the largest important size scales (Oliver et al. 2004). We present initial results from deep optical (U, g′, r′, i′) and Spitzer SWIRE (3.6–24 μm) imaging of 0.3 deg² in the SWIRE Survey validation field (VF) in the Lockman Hole, a field selected to have extremely low cirrus emission and a lack of bright radio sources. Deep K-band and VLA 2 cm imaging also exist, and this field will be imaged with Chandra ACIS-I to 70 ks depth in 2004 August. The full SWIRE survey will image ∼49 deg²

extraction apertures. Aperture corrections have been derived from stellar sources in the mosaicked data by the instrument teams, and these have been applied to correct to total fluxes. The IRAC flux calibration is believed to be correct within 3%, and the 24 \mu m calibration to 10%. There is an additional scatter resulting from color dependencies in the flat field that add a \leq 10% random error to the fluxes for all IRAC data. The calibration was confirmed for IRAC by comparison with the Two Micron All Sky Survey (2MASS), a robust extrapolation from the 2MASS K-band, since the IRAC bands lie on the Rayleigh-Jeans tail of the stellar spectral energy distribution (SED). For 10 stars in our field with 2MASS magnitudes, we extrapolated to a 24 \mu m flux density using Kurucz-Lejeune atmospheric models for MK class I, III, and V implemented in the Spitzer Science Center (SSC) stellar performance estimation tool, assuming G5 spectral type, confirming the calibration to better than 10%. The resulting catalogs were examined by eye and remaining spurious sources (from radiation, scattered light, etc.) were removed by hand. Details of the data processing are given in J. Surace et al. (2004, in preparation) and J. Shupe et al. (2004, in preparation).

The optical \( g' \), \( r' \), and \( i' \) data were taken in 2002 February and the \( U \) data in 2004 January using the MOSAIC camera on the Mayall 4 m telescope at Kitt Peak National Observatory (B. Siana et al. 2004, in preparation). The data were processed with the Cambridge Astronomical Survey Unit’s reduction pipeline following the procedures described by Babbedge et al. (2004). Fluxes were extracted within 2’76 apertures and corrected for the aperture using profiles measured on bright stars. An analysis comparing the 2’76 aperture-corrected magnitudes with total “Kron” magnitudes in the \( r' \) band indicated that at brighter than \(~21.5\) mag (Vega), significant numbers of galaxies have fluxes underestimated by the aperture photometry, and therefore our analysis is limited to galaxies fainter than this limit. Colors for the source samples were constructed from the aperture-corrected magnitudes.

The final depths for the Spitzer sample, at \(~5\) times the noise level, are given in Table 1. These depths are consistent with the 90% completeness limits as determined from the deviation of the observed number counts from a power law, and from simulated extractions of artificial sources injected into the data. The median achieved depths for extended objects (galaxies) in the optical bands, at the \(~90\%\) completeness levels for source extraction, derived in a similar fashion to the Spitzer data, are \( U = 24.9, g' = 25.7, r' = 25.0, \) and \( i' = 24.0. \)

Stars were removed statistically from the Spitzer catalog using predicted counts based on a near-infrared (NIR) Galactic stellar distribution model by Jarrett et al. (1994), based on the classic optical model of Bahcall & Soneira (1980). The model was verified using optical stellarity measures for objects associated with IRAC sources, and by matching star counts within a deep 2MASS catalog which reaches \(~2\) mag fainter than the all-sky 2MASS survey (Beichman et al. 2003). Stars outnumber galaxies at \( F_{3.6} \mu m \simeq 150 \mu Jy \) at this latitude (J. Surace et al. 2004, in preparation) and decrease rapidly in number relative to galaxies below that flux density.

### 2. RESULTS AND DISCUSSION

The detection statistics in Table 1 indicate that over the full SWIRE survey area \(~49\) deg\(^2\), we will detect \(~2.4\) million galaxies at 3.6 \( \mu m \) and \(~120,000\) in all four IRAC bands. At 24 \( \mu m \) the detection rate for the full survey will be better than for the \( VF \) discussed here because MIPS integration time has been doubled; therefore we estimate nearly \( 350,000\) galaxies detected in this band, and about \( 70,000\) of these in all four IRAC bands as well. At optical wavelengths we detect 27,911, 42,817, 39,308, and 30,230, stars plus galaxies at \( U, g', r', \) and \( i' \), respectively; 17,894 are detected in all four optical bands; 8626 in the combination \( r', 3.6 \mu m, 4.5 \mu m; \) and 325 are detected in all nine optical+IR bands.

We have compared the IR detection statistics to predictions from the models of Xu et al. (2003), model S3+E2, in Table 1. Model S3 includes dusty objects (spirals, starbursts, and AGNs), and E2 contains passively evolving stellar systems, i.e., spheroids. The Xu et al. model overpredicts SWIRE IR galaxy numbers by a factor of \(~2\) in the IR bands. The number counts results will be addressed by J. Surace et al. (2004, in preparation) and J. Shupe et al. (2004, in preparation).

Figures 2 and 3 present color-color plots that characterize the sample in \( g' \) to 24 \( \mu m \) color-color space. Only sources detected in all four bands shown in each figure are plotted; no limits are shown, for clarity. The figures show SED-redshift tracks of several galaxies with a broad range of intrinsic colors. These SEDs cover the range of colors exhibited by known objects throughout the \( U-24 \mu m \) wavelength range and \( 0 < z < 2. \) We do not expect many sources in the region of the figures occupied by rare objects like Arp 220 at low redshift, because our volume coverage at low-redshift space is small. A complete analysis of SWIRE galaxy colors relative to model predictions and SED tracks is beyond the scope of this paper, requiring thorough analysis of selection effects, photometric redshifts and K-corrections. Here we note a few basic results.

There is a very broad distribution of colors in these figures. Galaxies with little ongoing star formation will be relatively blue in the mid-IR because of a lack of dust emission, and also quite red in \( g'-r' \) because of domination by late-type stars,
and thus will be found toward the lower right of Figure 2, near the elliptical SED track (red curve). Indeed, there is a concentration of systems near this region. Moreover, the systems in the sample brightest in 3.6 μm (blue symbols) preferentially inhabit this region, indicating that these may be relatively nearby early-type systems. The stellar tracks also cross this region of Figure 2; using the stellar model described above we predict a maximum 0.13 star fraction in the 10 < $F_{3.6}$ μm < 150 μJy flux range, and 0.09 for 7.3 < $F_{3.6}$ μm < 10 μJy, focused strongly within ±0.2 mag of the stellar sequences. In Figure 3 the elliptical SED track lies off the figure to the bottom, as a result of a lack of 24 μm emission; objects in this lower right area are likely to be early-type spirals or unusually dusty spheroids.

Dusty systems will be more strongly detected at the longer wavelengths and therefore redder in the Spitzer [3.6]–[4.5] and [3.6]–[24] colors. There is a trend in both figures that these systems also tend to be the bluest in $g’$–$r’$, inhabiting the upper left of both figures. This is expected for systems that have both young complexes of dust-enshrouded star formation dominating the mid-IR and either (1) hot blue young stars visible in lower optical depth regions at optical wavelengths, or (2) a blue type 1 AGN visible in the optical, such as Mrk 231, which tracks into this area at $z > 2$ in Figure 3. It is notable that the most extreme systems (those toward the upper left of the figures), tend to be the fainter galaxies in the sample at 3.6 μm (red symbols). This could be interpreted as due to either preferentially more distant systems or lower luminosity systems; however, the complex selection and K-correction effects would need to be understood in order to investigate this further.

Some areas of the color-color diagrams are not well covered by the SED tracks. Of particular note are some unusually blue objects in [3.6]–[4.5], and mid-IR red sources at the upper left of Figure 3. Many additional extreme-colored objects with upper limits in one or more color are not shown in these figures. As an illustration of some of the most unusual objects populating the SWIRE sample, we have investigated a number of these sources with red [3.6]–[24] colors and unusually blue [3.6]–[4.5] colors, using the photometric redshift code Hyper-z (Bolzonella et al. 2000) to fit SEDs with a wide range of templates, redshifts, and $A_V$. We used our own library (M. Polletta et al. 2004, in preparation), the GRASIL library (Silva et al. 1998), and the Rowan-Robinson (2003) library. The Polletta et al. library contains around forty 1000 Å–20 cm templates for ellipticals, spirals, irregulars, starbursts, ultraluminous infrared galaxies (ULIRGs), and AGNs, derived from observed SEDs, including mid-IR Infrared Space Observatory (ISO) spectra and models following Berta et al. (2004). A more complete characterization and photometric redshift analysis of a larger SWIRE galaxy sample will be forthcoming (M. Rowan-Robinson et al. 2004, in preparation).

Investigating first the blue sources, we selected 603 sources with [3.6]–[4.5] < −0.3, significantly bluer than normal galaxies and stars, with S/N ≥ 10 in both bands. Fluxes were re-measured by hand for 193 of these objects with detections in a sufficient number of bands for SED analysis. We used the IPAC Skyview software to set background levels interactively, thus avoiding confusion with nearby sources and background contamination. In all, 67 sources were found to have valid colors. In about 8% of the remaining cases, the automated
source extractor measured a different region of a close or confused pair of sources, or of an extended source, in the two bands. Here 32% of the sources marginally miss the color cut on careful color reevaluation, 8% are cosmic rays or bad pixels, 36% have anomalous 3.6 \( \mu m \) fluxes caused by local background or other effects due to bright stars, and 16% have anomalous fluxes at either 3.6 or 4.5 \( \mu m \) with no obvious explanation. The last three categories represent a 76% anomaly rate among the 3.6 \( \mu m \) catalog, 40% anomaly rate among the entire S\( \lambda \) catalogue, and 6% anomaly rate among the entire S\( \lambda \) catalogue.

Fig. 4.—SEDs for five sources with [3.6] – [4.5] < −0.3 (lower five SEDs) and four sources redder than [3.6] – [24] = 7.5 mag. In most cases the uncertainties are smaller than the symbol sizes.

Another possible explanation for the blue [3.6] – [4.5] colors is a strong 3.3 \( \mu m \) polycyclic aromatic hydrocarbon (PAH) feature in the 3.5 \( \mu m \) band at low redshift (<0.1), but it would have to be considerably higher equivalent width than any such feature found in any of our templates. Also possible is a strong 2.35 \( \mu m \) CO bandhead absorption moving into the 4.5 \( \mu m \) filter at redshift ~0.7, requiring a young stellar population of red supergiants that is not diluted strongly by an older stellar population with a weaker absorption (Rhoads 1997). This might perhaps indicate a dominant ~10^7 yr old starburst in a fairly low mass galaxy. Alternatively, such a high equivalent width may indicate low metallicity.

In Figure 4 and Table 2 we present representative best fits for five blue sources (lower five SEDs; first five table entries). The 24 \( \mu m \) data points were downweighted in these fits so that they would not throw off the fit in the 3–5 \( \mu m \) region, with which we are primarily concerned here; mid-IR SEDs can have a wide range of shapes depending on details of geometry and astrophysics, which cannot be encapsulated in small libraries. The fitted redshifts range from 0.68 to 0.94, and the corresponding infrared luminosities range from \( L_{3,1000} \mu m = 10^3 \) to \( L_{3,1000} \mu m = 10^4 \) \( L_{\odot} \) these are star-forming galaxies and starbursts at moderate redshifts with moderate luminosities. The blue [3.6] – [4.5] region of the SED is only approximately fit, as anticipated, with deviations 0.8 to 2.2 \( \sigma \) high for the 3.6 \( \mu m \) points, and 4.3 to 7.9 \( \sigma \) low for the 4.5 \( \mu m \) data points (combined deviations of the [3.6] – [4.5] color from the template are given in the last column of Table 2). We present

15 \( H_0 = 71 \) km s\(^{-1}\) Mpc\(^{-1}\), \( \Omega_m = 0.27 \), \( \Omega_{\Lambda} = 0.73 \).
these fits as illustrative and not unique; fits at substantially
different redshifts are possible with different combinations of
templates and $A_V$ values. If this phenomenon is confirmed as a
real and substantial population with unusually blue 3–5 μm
SEDs, ideal fits will require modified template modeling out-
side the current libraries. We note that the fitted redshifts for all
of these objects are consistent with the hypothesis of a dominant
population of red supergiants with strong CO absorption at
2.35 μm redshifted into the 4.5 μm band. It will be most inter-
esting to discover whether Spitzer finds similarly blue colors in
any regions within nearby galaxies, where the stellar populations
and interstellar medium can be investigated in some detail.

We have also selected all sources redder than $3.6 - [24] =
7.5$ mag for investigation (see Fig. 3), requiring a detection at
$S/N > 5$ at 24 μm. Of 63 sources with $3.6 - [24] > 7.5$ mag,
42 were found to have valid colors this red on rederivation of
their fluxes by hand. The remainder are about evenly divided
between sources for which more than one 3.6 μm source likely
contributes to the larger beam 24 μm emission (a commonly
expected situation due to the large difference in beam profiles),
and spuriously low 3.6 μm flux densities caused by latents or
electronic offsets due to nearby bright stars. This latter cate-
gory of anomalies at 3.6 μm represents a $10/16075 = 0.06\%$
anomaly rate among the whole catalog, and 17% among the
selected red sources. As for the unusually blue $[3.6] - [4.5]$
sources, a high anomaly rate among color outliers is not
unanticipated.

The best-fit redshifts for four representative red sources
(Fig. 4, upper four SEDs; Table 2, last 4 entries) range from
0.37 to 2.85, with a luminosity range of $\log L_{3—1000,\mu m} = 11.1$
to 13.7 $L_{\odot}$. It is very difficult to obtain unique fits for some
objects of this type owing to the flatness of the SEDs and
the limited number of data points, and these fits should be
regarded as illustrative only, pending a thorough analysis of
the possible range of templates, redshifts, and luminosities
that can fit each of these sources. These objects appear to be
starbursts, ULIRGs, and AGNs with a wider redshift and lu-
iminosity range than the blue sources in Figure 4, including
some $z > 2$ objects with luminosities in the hyperluminous
object (HyLIRG) range. SWIRE is expected to be particularly
sensitive to high-redshift IR-luminous AGNs, which are ex-
pected to be bright in the very sensitive 24 μm band because
of warm circumnuclear dust. The high-redshift volume density
of HyLIRGs will be important for models for the early for-
mation of massive systems in the universe. Spitzer IRS
spectroscopy may prove essential for determining redshifts
and excitations for the reddest, optically faintest systems.

Support for this work, part of the Spitzer Space Telescope
Legacy Science Program, was provided by NASA through an
award issued by the Jet Propulsion Laboratory, California
Institute of Technology under NASA contract 1407.
