ABSTRACT

We propose an anisotropic generalization of the line correlation function (ALCF) to separate and quantify phase information in the large-scale structure of galaxies. The line correlation function probes the strictly non-linear regime of structure formation and since phase information drops out of the power spectrum, the line correlation function provides a complementary tool to commonly used techniques based on two-point statistics. Furthermore, it is independent of linear bias as well as the Gaussian variance on the modulus of the density field and thus may also prove to be advantageous compared to the bispectrum or similar higher order statistics for certain cases. For future applications, it is vital, though, to be able to account for observational effects that cause anisotropies in the distribution of galaxies. Based on a number of numerical studies, we find that our ALCF is well suited to accomplish this task and we demonstrate how the Alcock–Paczynski effect and kinematical redshift-space distortions can in principle be measured via the ALCF.

Key words: methods: statistical – large-scale structure of Universe.

1 INTRODUCTION

Galaxy surveys map a growing fraction of our Universe at ever increasing accuracy and are routinely used to test cosmological models. So far, agreement with the Λ cold dark matter (ΛCDM) model, a spatially flat universe primarily filled with dark matter and dark energy in the form of a cosmological constant, is excellent. Among their key science questions are the nature of dark matter, dark energy and the concrete model of the early Universe during which primordial density fluctuations were generated. A range of next-generation experiments, such as DESI (Flaugher & Bebek 2014), Euclid (Laureijs et al. 2011) and SKA (Dewdney et al. 2009), are designed to shed light on to these questions.

To make progress, it is crucial to optimize the amount of information extracted from the raw data that these experiments produce. Up until recently, the majority of the literature focused on two-point statistics, i.e. the power spectrum $P$ or the two-point function $\xi$, to analyse the observed distribution of galaxies. If the density field were Gaussian, two-point statistics would be sufficient to specify the statistical properties of matter fluctuations. However, during the non-linear stage of gravitational interaction, where structures like filaments, clusters and eventually galaxies form, any initial density field becomes highly non-Gaussian. Hence, by focusing on two-point statistics, a considerable part of the available information is ignored.

Consequently, new statistical measures have received significant attention. Besides computing higher order correlations (e.g. Peebles & Groth 1975; Peebles 1980; Frieman & Gaztanaga 1994; Scocimarro et al. 1998), it was suggested to employ genus statistics (Gott, Dickinson & Melott 1986; Hikage et al. 2002; Hoyle et al. 2002), Minkowski functionals (Mecke, Buchert & Wagner 1994; Hikage et al. 2003) and others. However, all of these measures suffer from the conceptual limitation that they are correlated with the two-point function. Thus, an intriguing idea is to exclusively analyse information not already contained in two-point statistics, i.e. phase information.

Correlations in the phases of Fourier coefficients emerge as a consequence of non-Gaussianity; since two-point statistics depend on the amplitudes of Fourier coefficients only, they are blind to phase information. The phase factors of the matter density field have been studied many years ago, but much of the original work in Ryden & Gramann (1991), Soda & Suto (1992) and Jain & Bertschinger (1998) focused on the evolution of single phases away from their initial values. A first statistic that described the phase difference between neighbouring Fourier modes was presented in Coles & Chiang (2000), Chiang (2001) and Watts, Coles & Melott (2003). Shortly thereafter, their considerations were generalized by Matsubara (2003), who quantified phase information by computing the joint probability density of phase factors, which illuminated its relation to higher order spectra (see also Hikage, Matsubara &

* E-mail: a.eggemeier@sussex.ac.uk
Suto 2004; Matsumura 2006). In Hikage et al. (2005), the probability densities were applied to a galaxy catalogue from the Sloan Digital Sky Survey, Data Release Two, giving constraints on bias models. Recently, a new measure for phase information, the line correlation function, was introduced by Obreschkow et al. (2013) as a spherically averaged three-point correlation of phase factors. In the follow-up paper (Wolstenhulme, Bonvin & Obreschkow 2015), it was computed perturbatively and related to the bispectrum and power spectrum at leading order.

The aim of this paper is to extend the line correlation function to account for line of sight and transverse distance scales separately. The introduction of such an anisotropic line correlation function (ALCF) opens up the possibility to detect anisotropies and distortions along the line of sight, which are inherently present in any galaxy survey due to redshift-space distortions.

The paper is organized as follows: after a brief review of the definition and properties of the line correlation function in Section 2, we present and test a modification in Section 3, which is capable of quantifying anisotropies. In Section 4 this new formalism is applied to simple mock fields, and we investigate the sensitivity to the Alcock–Paczynski (AP) effect and kinematical redshift-space distortions in comparison to results based on the two-point function. We conclude in Section 5.

2 THE ISOTROPIC LINE CORRELATION FUNCTION

In this section, we review the isotropic line correlation function (ILCF), which serves as the starting point for our generalization to the ALCF in Section 3.

2.1 Definition

Given a density field \( \delta(x) \), the ILCF measures correlations in its Fourier phase factors which are obtained by dividing amplitudes in Fourier space, 1

\[
\delta(x) \xrightarrow{\text{FT}} \delta_k \quad \text{whitening} \quad \epsilon_k \equiv \frac{\delta_k}{|\delta_k|} \xrightarrow{\text{IFT}} \epsilon(x).
\]  

The whitened density field \( \epsilon(x) \) is thus devoid of any information probed by two-point statistics. Consequently, the simplest measure of phase information must be based on the three-point correlator and since the whitening transformation tends to collapse elongated objects to thin line segments, as was observed in Obreschkow et al. (2013), these three points are chosen to be distributed equidistantly on a straight line. More precisely, and expressed in Fourier space, the ILCF is defined by

\[
l(r) = \frac{V^3}{(2\pi)^3 |\epsilon_k|} \int \int \int d^3k_1 d^3k_2 d^3k_3 \times \epsilon(k_1+x+k_2+r) \epsilon(k_1-x-ir) \epsilon(k_1) \epsilon(k_2) \epsilon(k_3),
\]

where \( D \) denotes the dimension of space, \( V \) the volume of the survey and \( \{ \} \) an ensemble average over all realizations of the density field. In writing equation (2) we adopted the same conventions as employed in Wolstenhulme et al. (2015).

The ILCF differs from the conventional three-point correlator of whitened density fields in two respects. First, it is multiplied by a prefactor \((r^D/V)^{1/2}\) and secondly, each field is convolved with a top-hat window function that cuts off high-frequency modes \(|k| > 2\pi/r\). These corrections are introduced to regularize the integral in the regimes of large and small scales, respectively. As discussed in Obreschkow et al. (2013), Fourier modes which are associated with scales larger than the longest physical correlation length or scales smaller than the lowest characteristic length obtain random phase factors that would cause the ILCF to be dominated by random noise.

It is important to reiterate that the ILCF is independent of amplitude information and for that reason not just a regularized integral of the bispectrum. It depends on the quantity \( \langle \epsilon_k \epsilon_k \epsilon_k \rangle = \langle \exp[i(\theta_k + \theta_k + \theta_k)] \rangle \), which can be determined by using the probability density function (PDF) of Fourier phases, \( P(\theta) \). This PDF was computed perturbatively for mildly non-Gaussian fields by Matsumura (2003), showing that it is not solely related to the bispectrum but a progression of all higher order spectra such as the trispectrum. Taking this result, Wolstenhulme et al. (2015) showed that the ILCF can be expressed to lowest order as follows:

\[
l(r) \approx \left( \frac{\sqrt{\pi}}{2} \right)^3 \left( \frac{r}{2\pi} \right)^{3D/2} \int \int d^3k_1 d^3k_2 \times \frac{B(k_1, k_2)}{\sqrt{P(|k_1|) P(|k_2|) P(|k_1+k_2|)}} \cos[(k_1-k_2) \cdot r],
\]

where \( P(|k|) \) and \( B(k_1, k_2) \) are the ordinary power spectrum and bispectrum. Accordingly, we can think of the ILCF as compressing information from all higher order spectra into a single function. Only in the case of weakly non-Gaussian fields does the dominant contribution stem from the bispectrum.

For evaluating the ILCF on a given density field, equation (3) is not particularly useful. However, we arrive at a simple prescription to extract the line correlation by assuming ergodicity and replacing the ensemble average in equation (2) by an average over all translations and rotations. Integrating out the translation vector \( x \) as well as the orientation of \( r \) thus gives

\[
l(r) = \frac{V^3}{(2\pi)^3 |\epsilon_k|} \int \int \int d^3k_1 d^3k_2 \times w_D(|k_1-k_2| r) \delta_{k_1} \delta_{k_2} \delta_{-k_1-k_2},
\]

where we have defined the rotational average of the exponential Fourier factor as

\[
w_D(k r) \equiv \langle e^{i \epsilon_k r} \rangle_R = \begin{cases} \cos(k r) & \text{if } D = 1, \\ J_0(k r) & \text{if } D = 2, \\ \sin(k r)/(k r) & \text{if } D = 3. \end{cases}
\]

A discretized version of equation (4) will be used for all numerical computations throughout this paper. Details on the implementation are given in Appendix A.

2.2 Properties and applications

The morphology of the cosmic web, composed of structures such as clusters, filaments and voids, is largely encoded in the phases of Fourier coefficients (for a demonstration, see e.g. Chiang & Coles 2000). Against this background, it is natural to assume that the ILCF is sensitive to these kinds of objects and, owing to its linear configuration, especially to filaments. In fact, after a more systematic analysis, Obreschkow et al. (2013) conclude that the ILCF is generally a measure for aspherical structures on scales \( \sim 2r \). This holds true for oblate and prolate objects alike, so that \( l(r) \) is able to probe both cosmic sheets and filaments.
Furthermore, they find two scaling relations depending on the size and density of the substructure. Letting $r_0$ denote its characteristic scale and $N$ the number of objects, their filling factor is given by $f = N V_{r_0}/V$, where $V_r$ is the volume of a $D$-dimensional sphere of radius $r_0$. A change of the characteristic scale or the number of objects has the following effect on the ILCF:

a) $r_0 \to \alpha r_0, f = \text{const.}$ \quad $\Rightarrow$ \quad $l(r) \to l(r/\alpha)$, \quad (6)

b) $N \to \alpha N$ \quad $\Rightarrow$ \quad $l(r) \to l(r) / \sqrt{\alpha}$. \quad (7)

The first relation specifically targets the behaviour of $l(r)$ under a rescaling of the substructure and therefore should not be confused with a scaling law resulting from power-law clustering. This can be derived from equation (3) and assuming the hierarchical model (e.g. Bernardeau et al. 2002), so that we have $B \sim P^2$. For a power-law spectrum $P(k) \sim k^\alpha$, we then get

$$l(\alpha r) = \alpha^{2/\alpha} l(r),$$

implying that the slope of $l(r)$ is less steep than that of the two-point function, which would scale as $\alpha^{-(D+\alpha)}$ for the same power spectrum. This conclusion was already found from numerical observations in Obreschkow et al. (2013). Furthermore, compared to conventional correlation functions, the second relation is also somewhat unintuitive: increasing the number of objects (and hence the clustering) causes a decrease in the amplitude of $l(r)$ instead of an increase, as one would expect. The cause of this feature is that the increased number of different translations and rotations of objects randomizes the phase factors, hence decreasing their correlation. This effect can also be understood by employing the halo model for a particular class of objects with orientational $\phi$, mass $m$ and density profile $\delta(r | \phi, m)$. For random positions of the haloes, one only needs to consider the one-halo term, so that, according to Smith & Watts (2005), the power spectrum and bispectrum become

$$\frac{P(|k|)}{(2\pi)^3} = \int d m \frac{n(m) m^2}{\bar{\rho}^2} \int \frac{d \phi}{|\Omega_D|} |U_k(\phi, m)|^2,$$  

(9)

$$\frac{B(k_1, k_2, k_3)}{(2\pi)^3} = \int d m \frac{n(m) m^3}{\bar{\rho}^3} \int \frac{d \phi}{|\Omega_D|} \int_{i=1}^{3} U_k(\phi, m),$$

(10)

where $\bar{\rho}$ denotes the total mass density of all haloes and $\Omega_D$ the surface area of the $D$-dimensional unit sphere. If all haloes have identical mass $M$, the mass function is given by $n(m) = N/V \delta^D(m - M)$ and we see that $P \propto 1/N$, i.e. $B \propto 1/N^2$. Hence, the combination of power spectra and the bispectrum in equation (3) gives rise to the scaling $\sim 1/\sqrt{N}$.

Being a relatively new tool in large-scale structure statistics, the ILCF has been applied only a few times so far. For instance, in Obreschkow et al. (2013) it was shown to be a significantly more sensitive tool to analyse properties of dark matter than the two-point function. The authors examined a series of cosmological $N$-body simulations with different warm dark matter masses, finding that $l(r)$ distinguishes those masses out to scales approximately five times larger than the two-point function. This feature is a direct consequence of the ILCF’s sensitivity to elongated structures and its ability to exclusively probe the non-linear stages of gravitational evolution. In another recent application (Alpaslan et al. 2014), the ILCF was used to identify a possibly new class of structure in the matter distribution, denoted as tendrils galaxies. These galaxies were spotted in the Galaxy And Mass Assembly (Driver et al. 2009) catalogue as remnants after all filament and isolated galaxies had been removed by appropriate detection algorithms. They appear in thin chains that extend into voids and display a different line correlation than those galaxies residing in the larger filaments. Finally, in Wolstenhulme et al. (2014), the ILCF was used to redshift trees using tree-level perturbation theory giving good agreement with direct estimates from $N$-body simulations. An analytic formula for $l(r)$ allows it to be modelled properly and opens the door for measuring various cosmological parameters.

### 3 The Anisotropic Line Correlation Function

Our ability to measure cosmological parameters with the line correlation function is intimately linked to our understanding of how it is influenced by effects that cause anisotropies in the distribution of galaxies (see Section 4). Not knowing the systematics of these effects increases uncertainties in the result. However, an anisotropic signal does not only add complications, its detection would also open up new avenues to probe and constrain the cosmological evolution in our universe. For this reason, it is a vital step to extend the ILCF to account for radial and transverse distance scales separately, allowing us to detect distortions along the line of sight.

Due to the corrections regularizing the ILCF, there are various possibilities to break rotational symmetry. In the following, we will therefore explore two different mode cut-offs, one being spherical as in the definition in equation (2), and the other one aspherical. We show that the latter is better suited to pick up anisotropies and test some of its properties.

#### 3.1 A spherical cut-off

Naively, it is straightforward to write down a two-dimensional analogue of the ILCF, especially when adopting the distant observer approximation, so that we can identify the line-of-sight direction with the $z$-direction — we simply restrict the angular average in our prescription in equation (4) to orientations of the transverse part of the vector $r$, giving

$$l(r_{\perp}, r_{\parallel}) = \frac{\nu^2}{(2\pi)^3} \left( \frac{r_B}{\nu} \right)^{3/2} \int_{|k_1|, |k_2|, |k_1 + k_2| \leq 2\pi/r} d^3k_1 d^3k_2 \times \cos \left( k_{\perp} \cdot r_{\parallel} \right) w_{D-1}(|k_{\perp} - k_{\perp}|, r_{\perp}) \times \delta_{k_1} \delta_{k_2} \delta_{k_1 + k_2},$$

(11)

Here, $r_{\perp} \equiv \sqrt{x^2 + y^2}$ and $r_{\parallel} \equiv z$ ($D = 3$) denote transverse and radial separations, respectively.

To see how well the function above distinguishes between statistically isotropic and anisotropic density fields, we consider a simple test case. We construct fields consisting of superpositions of aspherical haloes with a Gaussian density profile (see the upper panel in Fig. 1). While their centre positions are randomly distributed, their orientations are either drawn from a flat or a von Mises probability distribution. The von Mises distribution (Mardia & Jupp 1999; Watts et al. 2003) is a close approximation of the wrapped normal distribution — the analogue of the usual normal distribution on a circle — and depends on two parameters: $\mu$, the centre of the

---

\(^2\) All objects are assumed to have random positions and orientations.
distribution, and $\kappa$, which is a measure for its 'peakedness', i.e. increasing $\kappa$ causes a higher concentration about the centre. It reads

$$p(\phi | \mu, \kappa) = \frac{e^{\kappa \cos(\phi-\mu)}}{2\pi I_0(\kappa)},$$

(12)

where $I_0(\kappa)$ denotes the modified Bessel function of zeroth order. Furthermore, all fields here and in the remainder of this paper, if not stated otherwise, are set up in a two-dimensional box of sidelength $L$ with $N = 512$ grid cells (details are given in the captions of the corresponding figures). Extracting the line correlations of these sample fields according to equation (11) leads to the plot in Fig. 2. While $l(r_\perp, r_\parallel)$ only depends on $r = \sqrt{r_\parallel^2 + r_\perp^2}$ for the statistically isotropic fields, as expected, we do not observe a clear deviation from rotational symmetry in case of the anisotropic ones. This implies that the anisotropic signal is smeared over the whole $(r_\perp, r_\parallel)$-plane, which renders the spherical cut-off either tricky or ill-suited for the purposes given in the introduction of this section. For that reason, we consider an alternative method that incorporates an aspherical cut-off.

### 3.2 An aspherical cut-off

When exploiting our freedom to alter the mode cut-off, we must still ensure that it regularizes the integral for large scales and at the same time does not introduce any artificial anisotropies.

Therefore, we impose that it should satisfy the following two conditions:

1. the number of enclosed modes scales with $r^{-D}$,
2. the number of enclosed modes for each pair of values $(r_\perp, r_\parallel)$ with the same $r$ is constant.

There are still many possible cut-offs that satisfy these conditions; the one that we propose here is based on oblate spheroids of constant eccentricity (i.e. ellipses in the two-dimensional $(k_\perp, k_\parallel)$-plane). The semi-minor axis is supposed to scale as $2\pi r / r$ and more importantly, its orientation is chosen to be aligned with the vector $r = (r_\perp, r_\parallel)$, such that the spheroid rotates for varying scales. This choice is motivated by the fact that by filtering out all modes except those that predominantly belong to a given direction in $k$-space, objects are singled out that are aligned with the transverse direction in real space. This is demonstrated for a two-dimensional example in Fig. 3 which shows three different cut-offs and the corresponding whitened and filtered density fields. The green ellipse, for instance, belongs to a configuration where $r_\perp = 0$. Mathematically, this rotating cut-off may be expressed as

$$\theta_\kappa(k, r) \equiv k^2 r^2 + (\eta^2 - 1) (k \cdot r)^2 \leq 4 \pi^2,$$

(13)

where $\eta = \text{const.} \geq 1$. In two dimensions, we can convert equation (13) into polar form with $\psi$ the polar angle in the $(k_\perp, k_\parallel)$-plane and we get

$$k \leq \frac{2\pi/\eta r}{\sqrt{1 - \left(1 - \frac{1}{\eta^2}\right) \left(\frac{\pi}{\eta} \cos \varphi - \frac{\pi}{\eta} \sin \varphi\right)^2}}.$$

(14)

Thus, both semi-axes scale with $r^{-1}$, while the eccentricity of the ellipses is constant and given by $\varepsilon = \sqrt{1 - \eta^{-2}}$, as desired. For $\eta = 1$, we recover the original spherical truncation, while different
values of $\eta$ influence the signal-to-noise ratio and the sensitivity to anisotropies, as we will see in the following.

Since the eccentricity is left as a free parameter, we may ask whether there is a particular choice of $\eta$ that is optimal in the sense that it gives optimal signal-to-noise ratios for a range of scales. To determine if there is such a choice, we employ the same sample of statistically isotropic fields as above, consisting of Gaussian haloes with random positions and orientations. After computing the average line correlation and its variance from a number of realizations, we integrate out the angular dependence by averaging over all data points belonging to one of 25 radial bins of width $\Delta r \sim 0.0016 \, L$ that extend outwards from the origin $r = 0$. Normalizing the variance by the square of the average, we obtain an $r$-dependent signal-to-noise measure that we can compare for different values of $\eta$. The results of this analysis are shown in the upper panel of Fig. 4. All curves display a nearly continuous increase in the noise level, which is a consequence of a decreasing number of modes. However, the line correlation with spherical cut-off exhibits the smallest signal-to-noise (largest $\sigma_r^2/r^2$) for most scales, indicating that a different choice for $\eta$ is preferable. Indeed, we observe that $\sigma_r^2/r^2$ drops when the cut-off becomes more elliptical and eventually reaches a minimum that roughly lies in the interval $\eta^2 \sim [16, 32]$. For larger values, the noise level begins to rise again, such that the optimal $\eta$ must reside in the given interval. However, since the geometry of the cut-off matches that of the Gaussian haloes, one might suspect that this choice of parameter is optimal for this particular class of density fields only. To check this suspicion, we employ a second, more realistic set of density fields which are set up according to the Zel'dovich approximation, also based on 20 realizations. The resulting ALCFs are displayed in Fig. 4. After fixing $\eta$, we still have the freedom to adjust the profile of the cut-off, for instance to a Gaussian instead of a top-hat profile, and thus maximize the signal-to-noise ratio even further. However, for simplicity, we work with the top-hat filter in this paper.

Having settled on a definition of the ALCF, let us see how this choice influences the sensitivity to anisotropies. To that end, we repeat the test case from above where the fields are either statistically isotropic or anisotropic by giving the orientation of the Gaussian haloes a strong preference in the line-of-sight direction. The resulting ALCFs are displayed in Fig. 5. While the isotropic fields still give rise to rotationally invariant line correlations, we now see a clear anisotropic signal in the lower panel. Since the isocontour lines appear squashed and the signal peaks close to $r_\parallel = 0$, the whole transverse direction is enhanced. Given that most of the haloes point in the line-of-sight direction, this feature may appear counter-intuitive, but it is simply a continuation of the properties of the ILCF mentioned earlier. In Section 2.2, it was found that the amplitude of the ILCF decreases when the number of objects increases, which is reproduced here as well. In the following section, we study the properties of the ALCF more closely.

Figure 3. Cut-off ellipses for different pairs $(r_\perp, r_\parallel)$ and the resulting whitened and filtered density fields. Note that the blurring increases from top right to bottom left because of a decreasing number of modes.

Figure 4. Ratio of variance to squared average as a function of radial scale $r$ based on 20 realizations. Upper panel: density fields consisting of Gaussian haloes with random positions and orientations. Lower panel: fields set up according to the Zel'dovich approximation, also based on 20 realizations.

3 This result was obtained in a 2D analysis; we caution the reader that the optimal value for $\eta$ in 3D might be different.
3.3 Properties and examples

To characterize the properties of the ALCF and verify that it extends those of the ILCF in a consistent manner, we work again with the simple Gaussian halo fields and consider two anisotropic setups. For the first, we introduce a preferred direction, as already seen in the examples of the last two sections; for the second, we vary the scale of the haloes depending on their orientation.

3.3.1 Varying number densities

As before, the preferred direction is established by drawing the orientation angles of haloes from a von Mises distribution. We want to analyse how the strength of anisotropy, parametrized by the von Mises parameter $\kappa$, affects $l(r_\| , r_\perp)$, and in particular, whether there is a scaling relation similar to the one valid for the ILCF. Therefore, we first introduce a probability density of objects, $p_H(\phi)$, which is defined on the interval $[-\pi/2, \pi/2]$, such that

$$N \times p_H(\phi) \, d\phi = \text{number of objects in the bin } d\phi,$$

(15)

with $N$ being the total number of objects. Due to the symmetric geometry of the haloes, $p_H(\phi)$ is related to the probability density of orientation angles by

$$p_H(\phi) = p(\phi) + p(\phi + \pi) = \frac{\cosh [\kappa \cos (\phi - \mu)]}{\pi I_0(\kappa)},$$

(17)

where we have substituted in the von Mises distribution from equation (12).

As already suggested by Fig. 5 and in agreement with the interpretation of line correlations, we expect that the ALCF scales inversely with the probability density of objects. To verify this assertion, we compute the ALCF for five ensembles, each with $\mu = 0$ and a different value for $\kappa$. Afterwards, we extract the dependence on the angle $\phi$ from the two-dimensional function $l(r_\| , r_\perp)$ by averaging over a fixed number of points with constant $\phi$, but constrained to the radial interval $0 \leq r \leq R = 0.02L$ to exclude areas of large sample variance, i.e.

$$l(\phi) \equiv \frac{1}{R} \int_0^R \! dr \, l(r \sin \phi, r \cos \phi).$$

(18)

The results are displayed in Fig. 6; error bars originate from averaging over 100 realizations. We then fit these data to determine the scaling behaviour and to see whether we can recover the respective values of $\kappa$ that were used as input parameters for the construction of the fields with the model

$$l(\phi \mid \kappa, \alpha, \beta) = \alpha \left[ p_H(\phi \mid \kappa) \right]^\beta,$$

(19)

where we allow for a varying amplitude and exponent. Since $\alpha$ and $\beta$ should be universal (independent of $\kappa$), we perform a simultaneous $\chi^2$-fit to all five data sets using a different fitting parameter $\kappa$, and treating all data points as independent. The outcome of this fit along with the input parameters is summarized in Table 1, and shown for four example data sets as the thick solid lines in Fig. 6. We note that the fitted curves reproduce well the behaviour of the extracted data and we recover all peakedness parameters nearly within the error bounds. Moreover, taking the fitted values of $\alpha$ and $\beta$ to make a prediction for fields with a flat probability density (i.e. $p_H = 1/\pi$), we compute $l = 0.76 \pm 0.03$ while getting $l = 0.753 \pm 0.001$ numerically. Hence, we can confirm that the ALCF scales with the probability distribution of objects where it is likely that the parameter $\beta$ depends on the eccentricity of the cut-off ellipses.

Before moving on to the second test case, we briefly describe another interesting feature related to the probability density of structures. To that end, we generate fields that can be considered as an...
extreme case of the von Mises fields above: varying numbers of elongated Gaussians pointing either in radial or transverse direction with fixed $N = N_\perp + N_\parallel$. From Fig. 7, we observe that a strong signal in the line of sight is received when all objects are pointing in that direction, see panel (a). Even so, this signal can be altered significantly if a single object is aligned with the transverse direction, see panel (b). Adjusting $N_\perp$ and $N_\parallel$ until equality leads to a symmetric signal, see panel (c). This feature of the ALCF can be explained along the same lines as before: in (a), no information on structures in the transverse direction is present, while in (b) one object is present, which henceforth dominates due to minimal phase noise. Thus, care must be taken when using the plots of the ALCF to eyeball the strength of anisotropy.

3.3.2 Angularly varying scales

After having demonstrated the dependence on angular number densities, we turn our attention to angularly varying scales. Our sample halo fields are created as follows: for each orientation angle $\phi \in [-\pi/2, \pi/2]$, we determine the scale $\sigma_y$ of the Gaussian profile from the function

$$S(\phi | \sigma, \Delta \sigma, n) = \sigma + \Delta \sigma \cos(\omega \phi)$$

while keeping $\sigma_x = 0.006L$ fixed. As before, we intend to check how the ALCF is influenced by this anisotropy and especially how originally spherical lines of constant $l$ are deformed. In order to suppress any additional variations of the amplitude of $l(r_\perp, r_\parallel)$, we need to hold the filling factor constant, so that

$$f(\phi) = \frac{p_H(\phi)}{L^D} \frac{V_0(\phi)}{\sqrt{\pi} \sigma_x} \frac{\Delta \sigma}{\sigma} p_H(\phi) S(\phi) = \text{const.}$$

$$\Rightarrow \quad p_H(\phi) \propto 1/S(\phi),$$

where we resorted to the definition of $f$ in Section 2.2 and used $r_0 = \sqrt{\Delta \sigma \sigma}$ for $D = 2$. Consequently, when determining the scales from $S$, the respective orientation angles must be drawn from the distribution $1/S(\phi)$. This distribution is realized using the method of inverse transform sampling (Devroye 1986). With that, we set up two ensembles of fields for the cases $\omega = 2$ and 4, where we chose $\sigma = 0.02L$ and $\Delta \sigma = 0.01L$. After evaluating the line correlation function, we extract two isocontours for each $\omega$, convert the Cartesian coordinates into 21 angular bins and average over 100 realizations which gives the data points in Fig. 8.

Since the average characteristic scale $r_0 = \sqrt{\sigma_1 \sigma_2}$ is modified by the angle-dependent factor $\sqrt{1 + \Delta \cos(\omega \phi)}$ with $\Delta \equiv \Delta \sigma/\sigma$, we may expect that any isocontour at scale $R$ for a statistically isotropic field is distorted as

$$R \to R \left[1 + \Delta \cos(\omega \phi)\right]^\gamma,$$

with an unknown exponent $\gamma$ which, as for the parameter $\beta$ in the previous section, presumably depends on the eccentricity of the cut-off ellipses. We therefore fit the extracted contours with the model

$$r(\phi | R, \Delta, \gamma) = R \left[1 + \Delta \cos(\omega \phi)\right]^\gamma,$$
using different fitting parameters $R_k$, but equal $\Delta$ and $\gamma$ throughout. The results from a simultaneous fitting procedure equivalent to the one above are represented by the solid lines in Fig. 8, with the corresponding best-fitting values given in Table 2.

We observe that the data are fitted well by the model, showing the expected distortion of radial scales, i.e. a stretching for those angles where the characteristic scale is larger. Furthermore, the fitted values for $R$ match well to the same isocontours of statistically isotropic fields, which were estimated from an ensemble of randomly oriented haloes with fixed scales $\sigma_z = 0.006 L$ and $\sigma_z = \sigma = 0.02 L$. However, the parameter $\Delta$ is slightly off, which can be attributed to the scatter in the data and the fact that the fit is quite sensitive to both $\Delta$ and $\gamma$.

4 APPLICATION TO REDSHIFT-SPACE DISTORTIONS

Anisotropies in the distribution of galaxies occur naturally whenever the redshifts and positions (angles) acquired in a survey are converted into physical distances. They may be of geometric or kinematic nature, denoted by the AP effect and (dynamical) redshift-space distortions, respectively. In this section, we analyse whether these observational effects are picked up by the ALCF and how these results compare to the ones from conventional two-point statistics. Since we primarily aim for a proof of concept, we will continue to use the two-dimensional halo and Zel’dovich mock fields introduced above.

4.1 The AP effect

The conversion of the redshift difference and angular separation of a pair of galaxies to a physical distance depends on two basic cosmological quantities: knowledge of the Hubble rate $H(z)$ is required for the computation of the line-of-sight separation, and the angular diameter distance $D_A(z)$ is required for the transverse separation,

$$r_\parallel = \frac{d}{dz} \Delta z = \frac{d}{dz} \left( \int_0^z \frac{c dz'}{H(z')} \right) \Delta z = \frac{c \Delta z}{H(z)} \quad (25)$$

$$r_\perp = D_A(z)(1 + z) \Delta \theta. \quad (26)$$

Consequently, creating a spatial map of the universe hinges on a cosmological model that has to be assumed a priori; if this model differs from the true cosmology, the deduced distances are wrong, causing distortions in the clustering signal. The first who proposed to use this effect as a probe for cosmological parameters were Alcock and Paczyński (Alcock & Paczyński 1979). By considering an object whose intrinsic shape is known to be spherical, they deduced that measuring distortions from sphericity can be used to constrain the combination $H(z) D_A(z)$, and in turn, for instance, the equation of state parameter of dark energy. However, in practice, there are no objects, which are sufficiently spherical or whose length-scales are known to sufficient accuracy, to perform the AP test on individually. Instead, one resorts to statistical standard rulers, that is, length-scales that are statistically imprinted on large-scale structures, such as the one set by baryon acoustic oscillations (BAOs); since BAOs are primarily a linear phenomenon, their signal is not considerably affected by non-linear physics. Thus, by measuring the position of the BAO peak and comparing it to the theoretical prediction, it is possible to conduct an AP test (Blake & Glazebrook 2003). However, with the ever increasing volume coverage of galaxy surveys, an alternative has become feasible, in which a complete model of a given statistical measure, incorporating a possibly wrong choice of cosmology, is fitted to the data (see e.g. Ballinger, Peacock & Heavens 1996; Okumura et al. 2008; Padmanabhan & White 2008). A similar method could be employed based on the ALCF.

To quantify the impact of the AP effect on the line correlation function, we first parametrize the mismatch between true and assumed cosmology by two squashing factors (following the notation of Ballinger et al. 1996):

$$f_\parallel = \frac{H_A(z)}{H(z)}, \quad f_\perp = \frac{D_A(z)}{D_{A,a}(z)}, \quad (27)$$

and in the following the subscript ‘$a$’ indicates quantities derived from the assumed cosmology. From equations (25) and (26), we see that assumed and true distance scales are related by the matrix

$$r_a = S r, \quad S = \begin{pmatrix} f_\parallel^{-1} & 0 \\ 0 & f_\perp^{-1} \end{pmatrix}. \quad (28)$$

Due to number conservation, the overdensity does not change in the assumed coordinate system, so that $\delta_a(x_a) = \delta(x)$, which implies for the two-point function

$$\xi_a(r_a) = \xi(r) = \xi(S^{-1} r_a). \quad (29)$$

Thus, any squashing of galaxy separations directly translates to an equivalent squashing of the isocontours of $\xi$. To compute the analogue effect for the ALCF, we need to be more careful because of the scale-dependent cut-off and prefactor. For that reason, we transform $l_i(r_{\perp,a}, r_{\parallel,a})$ piecewise and start from the whitened and filtered density field in the assumed coordinate system, which we write as a convolution between $\epsilon$ and the cut-off $\Theta$ in real space,

$$\epsilon_a = \Theta_{a,r_a}(x_a) = V_a \int_{\Theta(\epsilon_a,k_{\parallel a},r_a) \leq 4\pi} d^3k_{\parallel a} e^{i k_{\parallel a} x_a} \epsilon_{a,k_{\parallel a}} = V_a |S|^{-1} \int_{\Theta(S^{-1} \epsilon, k_{\parallel a}) \leq 4\pi} d^3k e^{i k \cdot S^{-1} x_a} \epsilon_k. \quad (30)$$

Here, we used that the Fourier modes scale inversely to spatial scales and employed the identity $\epsilon_{a,k_{\parallel a}} = \epsilon_k$, which is another direct consequence of number conservation. Shifting the $S$-matrix from $k$ to $r_a$ in the cut-off function causes an additional term that can be computed from the definition of $\Theta$ in equation (13), yielding

$$\Theta(S^{-1} k, r_a) = \Theta(k, S^{-1} r_a) + (f_\perp - f_\parallel) \left( k_{\perp}^2 r_{\perp,a}^2 - k_{\parallel}^2 r_{\parallel,a}^2 \right) = \Theta(k, S^{-1} r_a) + \delta_F(k, S^{-1} r_a), \quad (31)$$

$$\delta_F(k, r) \equiv (1 - F^2) \left( F^{-2} k_{\perp}^2 r_{\perp}^2 - k_{\parallel}^2 r_{\parallel}^2 \right), \quad (32)$$

Table 2. Expected and fitted parameters for density fields with scales of explicit angular dependence.

where $F$ is the ratio of $f_1$ to $f_∥$. Plugging this result back into equation (30) gives

$$
\epsilon_a \Theta_{a, r_a}(x_a) = V \int \frac{d^3k}{k^3} e^{i k \cdot S^{-1} x_a} \epsilon_k
$$

$$
= \epsilon \Theta_{F, S^{-1} r_a}(S^{-1} x_a),
$$

(33)

where we identified $V/F$ with the true volume and let $\tilde{\Theta}_F$ denote the altered cut-off that reverts to the original one for $F = 1$. Having thus determined the relation between the whitened and filtered density field in the assumed cosmology to the one in the true model, we still need to transform the prefactor. Using equation (28) again, we arrive at

$$
r^2_{a,\parallel} + r^2_{a,\perp} = f^2_{\parallel} r^2_1 + f^2_{\perp} r^2_\perp = (f^2_{\parallel} + f^2_{\perp}) r^2_1 + f^2_{\perp} r^2_\perp
$$

$$
= f^2_{\perp} r^2_\perp \left[ 1 + (F^2 - 1) \mu^2 \right],
$$

(34)

where $\mu$ is the cosine of the angle to the line of sight, i.e. $\mu = r_\perp/r$. All in all, we get

$$
n_{\parallel}(r_a) = F^2 \left[ 1 + (F^2 - 1) (S^{-1} \mu_a)^2 \right] \frac{\Phi}{F} \left( S^{-1} r_a \right),
$$

(35)

where

$$
(S^{-1} \mu_a)^2 = \frac{f^2_{\parallel} r^2_{a,\parallel} + f^2_{\perp} r^2_{a,\perp}}{f^2_{\parallel} r^2_1 + f^2_{\perp} r^2_\perp},
$$

(36)

and the notation $\frac{\Phi}{F}$ refers to the line correlation function where all cut-offs have been modified by the function $\delta_F$ as in equation (33). Equation (35), which is the main result of this section, relates the correlator for the assumed cosmology at scale $r_a$ to the modified (but true) one at the shifted position $S^{-1} r_a$. As in equation (29) for the two-point function, it encodes the impact of the AP effect on the ALCF and can either be used as a basis for fitting existing data to extract $f_\parallel$ and $f_\perp$ or for simulating it. Since the effect is not immediately evident by inspecting equation (35), we compute the assumed line correlation function from a set of true fields with varying values for the squashing parameters.

To visualize the AP effect and enable comparison with the two-point function, we decompose the data in the $(r_\perp, r_\parallel)$-plane into multipoles. As our density fields are two-dimensional, the $n$th-order multipole is calculated via

$$
f_n(r) = \frac{1}{\pi} \int_{-\pi}^{\pi} f(r \sin \phi, r \cos \phi) \cos(n \phi) d\phi,
$$

(37)

where $f$ is either $\xi$ or $l$, and the sign convention is chosen such that an enhancement of the transverse direction compared to the line of sight translates into a positive signal for the quadrupole $f_2$. Using equation (35), we determine the monopole and quadrupole for an ensemble of Gaussian halo and Zel’dovich density fields with varying $f_\parallel$, but fixed $f_\perp$. The corresponding quadrupole-to-monopole ratios are plotted in the upper panels of Figs 9 and 10. We notice that in both cases the AP effect introduces a clearly visible anisotropy by means of an increasing quadrupole signal with rising $f_\parallel$. Interestingly, the quadrupole is positive for small scales, meaning that the ALCF is squashed. However, with increasing scale the quadrupole changes sign, turning the initial squashing into a stretching of the line of sight. After attaining a maximum, the amplitude of the quadrupole decreases, but remains negative throughout.

Note that $\delta_F$ arises purely as a consequence of the first term in equation (13). Equation (31) and all of the following expressions are hence equally valid for the original spherical cut-off.

Figure 9. Quadrupole-to-monopole ratio for the ALCF (upper panel) and two-point function (lower panel), derived from a set of 50 Gaussian halo fields. The AP effect is simulated via equation (35) with $f_\parallel$ ranging between 1 and 1.5 while $f_\perp = 1$. Shaded areas mark 1σ uncertainties.

Figure 10. Same as Fig. 9, but based on 50 realizations of Zel’dovich density fields.
In comparison, the quadrupole-to-monomonopole ratio of the two-point function, which is displayed in the lower panels of Figs 9 and 10, is positive for all scales, reflecting the squashing expected from equation (29). Although being unintuitive, the behaviour of the ALCF can be understood in light of the discussion in Section 3.3. If the separations of galaxies are squashed in a given direction, the scale and orientation of the structures in the density field change. In the case considered here (squashing in the line-of-sight direction), a preference for structures to be aligned with the transverse direction arises. This results in the enhanced radial signal since the ALCF scales inversely with the number density of objects.

While the ALCF is indeed capable of detecting the AP effect, the two-point function appears to be superior in telling apart different $f$ from each other for both sets of fields. Its quadrupole-to-monomonopole ratio increases with scale, which renders $\xi$ sensitive to $f$ on all scales. On the other hand, the $1\sigma$ error regions begin to overlap at $r \sim 0.02 L$ for the line correlation function, which implies that estimates based on $\xi$ will be statistically more significant. This is a reasonable result owing to the number of modifications in equation (35), which tend to influence the ALCF in converse directions. Assuming $F > 1$ in the following, we first note that the modified cut-off gives rise to an increase in the ALCF’s amplitude in the line-of-sight direction, as can be verified empirically. Conversely, the distortion of the prefactor attains a minimum for $r_{\perp} = 0$ and accordingly strengthens the transverse direction compared to the line of sight. The same is true for the modification of scales by the matrix $S^{-1}$, given that $l(r)$ is a decreasing function of $|r|$. As a consequence, the net effect of the AP squashing on the ALCF is smaller than for the two-point function, where only one kind of distortion effect is present.

However, we would like to reiterate that the ALCF uses phase information, which is complementary to the amplitude information retained in the two-point correlator. Thus, both estimators can be used in conjunction in realistic applications to tighten constraints.

### 4.2 Kinematical redshift-space distortions

Another consequence of measuring redshifts instead of physical distances is distortions due to the peculiar velocity of galaxies. Apart from the Hubble flow, they also contribute to the redshift and thus cause the galaxies to appear displaced along the line of sight.

Since galaxies result from the structure formation process through gravity, their peculiar velocities are induced by gravity as well. On large scales, where structures have not yet fully collapsed, all matter tends to fall into the nearest overdensity. For that reason, a given galaxy that resides on the near-edge of a large cluster tends to move away from us, increasing its redshift. Consequently, its apparent position is closer to the centre of the overdensity. A galaxy on the far-edge of the cluster would behave in the opposite way, so that it appears to be closer to us than it actually is. We therefore observe that structures on those large scales look squashed in the radial direction which is known as the Kaiser effect (Kaiser 1987). He showed that in the distant observer limit, the power of scales that are aligned with the line of sight is boosted by the factor $1 + f\mu^2$ ($\mu$ being the cosine to the line of sight), so that the redshift-space dark matter power spectrum is given by

$$P(k) = (1 + f\mu^2)^2P(k).$$

The amplitude of the distortion depends on the logarithmic growth rate $f$, which is related to the matter content in the universe and, according to Peebles (1980), well approximated by the power law $f \approx \Omega_m^{0.5}$. Thus, measuring the Kaiser effect enables us to put constraints on the matter density or, if combined with an independent measurement of $\Omega_m$, on the theory of general relativity.

At much smaller, non-linear scales, objects within already collapsed structures acquire random virialized velocities which smear the structure in the line-of-sight direction leading to a characteristic shape that seems to point at the observer. Somewhat misleadingly, these shapes were called *Fingers of God* (Jackson 1972). Lacking an analytical description, several empirical models exist that try to mimic this small-scale effect by smearing the density field along the line of sight with the PDF of velocities (Jackson 1972; Hawkins et al. 2003). The models mainly differ in the assumption of how these velocities are distributed; commonly, it is expected that they acquire a Maxwellian distribution, which gives rise to a multiplicative damping term for the power spectrum of the form

$$F_{\text{FoG}}(k, \mu) = \left(1 + \frac{k^2\mu^2\sigma_p^2}{2}\right)^{-1}.$$ (39)

The pairwise velocity dispersion $\sigma_p$ is approximately of the order of $\sigma_p \sim 400\, \text{km s}^{-1}$ (Hawkins et al. 2003).

The goal for the remainder of this section is to estimate how the ALCF is influenced by these kinematical redshift-space distortions. Hence, we take appropriate sets of mock fields that simulate the Kaiser or Fingers-of-God effect and proceed as in the preceding section by computing the quadrupole-to-monomonopole ratio. In the Zel’dovich approximation, the velocities are simply proportional (with proportionality factor $f$) to the displacement field and hence the Kaiser effect can be easily incorporated by displacing particle positions by this additional line-of-sight component. This leads to distorted density fields that seem to be derived from redshift space. In Fig. 11, we plot the quadrupole-to-monomonopole ratios for
both the ALCF and the two-point function, estimated from these fields where we leave $f$ as a free parameter which varies between 0.25 and 0.75. While the two-point function displays the anticipated behaviour, i.e. a squashing in the line-of-sight direction that becomes more prominent for increasing $f$, the ALCF exhibits a more complex quadrupole signal. On small scales, the quadrupole is negative, indicating a stretching in the line of sight, before it changes sign at a cross-over scale that seems to shift towards larger values, suggesting a squashing in the line-of-sight direction, before it changes sign at a cross-over scale that seems to shift towards larger values. For higher $f$, there are no structures aligned with the transverse direction. However, for the two-point function, since the Kaiser effect shrinks the radial dimension of structures in the density field, the enhancement of the transverse direction of the ALCF appears reasonable based on the discussion in Section 3.3.2.

Since the Zel’dovich approximation cannot account for the Fingers-of-God effect, we create a simplified setup which mimics these small-scale distortions. First, we draw random positions that are taken to be the centre points of haloes. We assume that these haloes have a spherical Gaussian density profile and accordingly draw particle positions in each halo from a Gaussian distribution. Thereafter, we determine velocities from a Maxwellian distribution and displace all particles proportionally to their velocity along the line of sight. Computing the quadrupole-to-monopole ratio gives the plot in Fig. 12, showing a distinctive negative signal which confirms the stretching of structures in the line of sight. In this simplified case, the Fingers-of-God effect establishes a clear preference of the line-of-sight direction, with no structures being aligned with the transverse direction. However, as we have seen in Section 3.3.1, the signal of the ALCF may change drastically if this is the case, so it would be interesting to see how the Fingers-of-God effect appears in a realistic $N$-body simulation that also contains filamentary structures in all directions.

5 CONCLUSION

In this paper, we presented an extension to the recently proposed line correlation measure (Obreschkow et al. 2013) that enables the identification of anisotropies in a given density field. The line correlation function is an estimator that relies purely on the phases of the density field and thus probes information not contained in ordinary two-point statistics.

Starting from a generalization of the originally defined line correlation function, we noticed that anisotropies tend to be smeared over the plane of radial and transverse separations. For that reason, we introduced a novel mode cut-off scheme, which plays an integral part in the definition of the ALCF. We showed that this new function produces better signal-to-noise ratios and, by using simple test fields as replacements for real observational data, we demonstrated that it extends the properties of the original line correlation function in a consistent manner. In particular, we observed that the altered cut-off method allows for a clear distinction between statistically isotropic and anisotropic fields, and we showed that it is sensitive to angularly varying number densities and scales of structures.

An interesting point that could be explored in future research is the optimization of the cut-off function. While we have demonstrated that our choice of cut-off geometry with $n^2 = 32$ improves the signal-to-noise in the line correlation function for two morphologically different density fields, we have not shown that this filter actually maximizes the signal-to-noise. To achieve that, one has to carry out a more systematic analysis involving the determination of the line correlation function covariance, which is beyond the scope of the current paper.

In the second part, but still aiming primarily for a proof of concept, we considered observational effects, like the Aloc–Paczyński, Kaiser and the Fingers-of-God effect. We derived the relation between the assumed and true line correlation functions when redshifts and angles of galaxies are transformed with a wrong prior cosmology and computed quadrupole-to-monopole ratios for all three effects, estimated from simple mock fields. We found that the line correlator is capable of detecting them, displaying different systematics than the two-point function. While its sensitivity appears to be somewhat worse than that of the two-point function, this is still a promising result: since the information probed by both measures is independent from each other, it is conceivable that employing both statistics can lead to tighter constraints on cosmological parameters than, for instance, a combination of the two- and three-point function.

To investigate these prospects, a more detailed study of redshift-space distortions is necessary. It is inevitable to employ $N$-body simulations to analyse both the Kaiser and Fingers-of-God effect in a realistic setup, and it would be interesting to see whether the cross-over scale, which was observed in Fig. 11, is indeed a persistent feature. To understand this behaviour, additional analytical studies are desirable as well. A possible ansatz for such an investigation could be to reformulate the combination of bispectrum and power spectra that appears in the perturbative expression of the line correlation function (see equation 3) in terms of the perturbative kernels in redshift space which were derived in Scoccimarro, Couchman & Frieman (1999). Finally, it remains to be seen which parameters the line correlation function is able to constrain and to what accuracy.

In addition to the independence of information probed by the two-point and line correlation functions, both measures have different systematics, which allows the breaking of degeneracies in the parameter estimation. An interesting example is the logarithmic growth rate which describes the strength of the Kaiser effect (see Section 4.2). Due to the fact that we are measuring galaxy positions, which are biased tracers of the underlying dark matter distribution,
the two-point function is actually only sensitive to the combination $\beta = f/b$, where $b$ is the linear bias parameter. On the other hand, the line correlation function is independent of linear bias and hence constrains $f$ directly, meaning that a joint analysis might allow for the determination of $f$ and $b$ separately. We leave these exciting new avenues for a future research project.

ACKNOWLEDGEMENTS

We thank Danail Oboreschkov as well as the anonymous referee for their valuable feedback on the draft. We are also grateful for further comments from Diana Battefeld and Rizwan Barbhuiya. AE acknowledges the STFC for his studentship funding.

APPENDIX A: NOTES ON THE IMPLEMENTATION

In this appendix, we briefly comment on our numerical implementation of the line correlation function and show convergence tests.

We adopt a standard numerical discretization scheme: the density field is contained in a finite cubic box of sidelength $L$ on which we impose periodic boundary conditions. The box is subdivided into an even number, $N$, of cells per side with the regular Cartesian grid spacing $\Delta x = L/N$. Accordingly, in Fourier space the box has a sidelength $2\pi N/L$ with spacing $\Delta k = 2\pi/L$ and Nyquist frequency $k_N = \pi N/L$. Upon discretization using this scheme, integrals in configuration and Fourier space become

$$\int d^3 x \: f(x) \rightarrow \left(\frac{L}{N}\right)^3 \sum \frac{D}{D} f(x), \quad (A1)$$

$$\int d^3 k \: k \: f_k \rightarrow \left(\frac{2\pi}{L}\right)^3 \sum k \: f_k. \quad (A2)$$

Applying these rules to the prescription of the line correlation function in equation (4), we get

$$l(r) = \left(\frac{r}{L}\right)^3 \sum_{|k_1|,|k_2| < \pi L} w_D(k_1-k_2|r) \times \delta_{k_1} \delta_{k_2} \delta_{x-x} \delta_{x-x}^2$$

where $\mathcal{R}$ denotes a rotation matrix and the mode cut-off is written as $\delta_{k_1}$ which stands for the convolution of $\delta(x)$ with an appropriate filter function $\Theta_x$. Discretizing the equation above gives

$$l(r) = \left(\frac{r}{L}\right)^3 \sum_{|k_1|,|k_2| < \pi L} \sum_{x} \Theta_x (x) \times \Theta_x (x + \mathcal{R} x) \epsilon_\delta (x - \mathcal{R} x) \epsilon_\delta (x - \mathcal{R} x)$$

$$= \left(\frac{r}{L}\right)^3 \sum_{|k_1|,|k_2| < \pi L} \sum_{x} \Theta_x (x) \times \Theta_x (x + \mathcal{R} x) \epsilon_\delta (x - \mathcal{R} x) \epsilon_\delta (x - \mathcal{R} x)$$

where we replaced the summation over all $x$ by the fast Fourier transform (FFT) algorithm. Since we can quickly transform back and forth between Fourier and configuration space using the FFT algorithm, it is advantageous to compute the convolution as well as the shift in position in Fourier space. Hence, letting $\theta(k, r)$ either denote the original or modified cut-off in equation (13), we have

$$\epsilon_\delta (x + r) = \text{FFT}^{-1} \{ \epsilon_k \epsilon^{ik} \theta(k, r) \}.$$
Equations (A6) and (A7) form the basis of all numerical computations in this paper.

Let us consider a test case that allows us to compare with analytic results and study the convergence of the implementation with increasing $N$. We create density fields consisting of $N_H$ spherical Gaussians with equal standard deviation $\sigma$. In this case (see equations 9 and 10),

$$\frac{B(k_1, k_2, k_3)}{\sqrt{P(k_1)P(k_2)P(k_3)}} = \frac{V}{(2\pi)^3 N_H},$$

(A8)

such that for $D = 2$ and, after integrating out one azimuthal angle, equation (3) gives

$$l(r) = 2 \left(\frac{\sqrt{\pi}}{2}\right)^3 \left(\frac{r}{2\pi}\right)^3 \sqrt{\frac{V}{N_H}} \int_0^{2\pi} dk_1 \int_0^{2\pi} dk_2 \int_{-1}^1 \frac{d\mu}{\sqrt{1 - \mu^2}} J_0(|k_1 - k_2| r),$$

(A9)

where $\mu = \cos \angle(k_1, k_2)$ and its upper limit is given by $\mu_{\text{cut}} = \min[1, \max[-1, \{(2\pi/r)^2 - k_1^2 - k_2^2]/(2k_1k_2)]$. Equation (A9) can be integrated easily, for instance using a Monte Carlo approach, to yield the analytic answer. However, to compare with the numerical result, we need to take care of a subtlety which arises in the whitening process: whenever the amplitude of Fourier coefficients drops below a certain threshold value, their phase factors are not resolved properly anymore; in order to avoid the introduction of artefacts, we need to cut out these coefficients.\footnote{This feature is due to the peculiar nature of the test fields considered here. Realistic density fields are unlikely to exhibit unresolved phase factors.}

Another way to deal with unresolved phase factors is the superposition of small amplitude to ensure that Fourier coefficients with nearly vanishing amplitudes acquire random phases. This procedure guarantees that no artificial information compromises the signal: since the GRF is uncorrelated to the Gaussian haloes and assuming that it has zero mean, we only obtain a contribution to the overall power spectrum,

$$P(k) = P_d(k) + P_{\text{GRF}}(k).$$

(A10)

Doing so complicates equations (A8) and (A9), but for known $P_{\text{GRF}}(k)$, it is still possible to find the analytic answer via Monte Carlo integration.

The upper panel of Fig. A1 shows a comparison between numerical and analytic results. We see that to the right of the vertical line, which indicates the threshold scale $r_{\text{th}} = 2\pi/k_{\text{th}}$, the data points approach the dashed line, which is the analytic result based on equation (A9). Below $r_{\text{th}}$, the effect of cutting out unresolved phase factors becomes important and produces the oscillatory behaviour, which can be exactly reproduced for both methods if we account for the corresponding modifications in equation (A9). Thus, this test case serves as a convincing consistency check between our numerical scheme and the perturbative expansion of the line correlation function.

Finally, the lower panel of Fig. A1 displays a convergence test for a varying number of grid points using a single realization of the test fields above. The plot clearly shows that our method converges quickly, indicating only small discrepancies for $N$ as low as $N = 128$. All of our computations were carried out with $N = 512$ grid points.
