Abstract

In mitotic cells, the cyclin-dependent kinase (CDK) subunit protein CKS1 regulates S phase entry by mediating degradation of the CDK inhibitor p27. Although mature neurons lack mitotic CDKs, we found that Cks1 was actively expressed in post-mitotic neurons of the adult hippocampus. Interestingly, Cks1 knockout (Cks1−/−) mice exhibited poor long-term memory, and diminished maintenance of long-term potentiation in the hippocampal circuits. Furthermore, there was neuronal accumulation of coflin-actin rods or coflin aggregates, which are associated with defective dendritic spine maturation and synaptic loss. We further demonstrated that it was the increased p27 level that activated coflin by suppressing the RhoA kinase-mediated inhibitory phosphorylation of coflin, resulting in the formation of coflin aggregates in the Cks1−/−.
neuronal cells. Consistent with reports that the peptidyl-prolyl-isomerase PIN1 competes with CKS1 for p27 binding, we found that inhibition of PIN1 diminished the formation of coflin aggregates through decreasing p27 levels, thereby activating RhoA and increasing coflin phosphorylation. Our results revealed that CKS1 is involved in normal glutamatergic synapse development and dendritic spine maturation in adult hippocampus through modulating p27 stability.

**Key words:** cyclin-dependent kinase, hippocampus, long-term potentiation, RhoA, synaptic plasticity

### Introduction

The establishment of long-term memory requires structural plasticity of dendritic spines, which contributes to altered synaptic strength between neurons. Recent studies have begun to unravel an increasing number of molecular partners that underscore this process (Rochefort and Konnerth 2012), some of which are also involved in non-neuronal cellular processes. The functions of these molecules range from sculpting the cytoskeleton during mitosis and cellular migration, to control of the cell cycle (Odajima et al. 2011).

CKS1 was first identified as a cyclin-dependent kinase (CDK) interacting protein that participates in cell-cycle control (Pines 1996). In the mitotic cell cycle, mammalian CKS1 binds CDK1 and CDK2. Expression of CKS1 is particularly elevated in many aggressive human cancers, where its oncogenic role has been ascribed to a second function for the protein as a cofactor to the ubiquitin ligase complex, SCFSKP2 (Hao et al. 2005). SKP2 ubiquitylates and therefore mediates proteasomal-dependent degradation of a number of important substrates that control G1—S phase transition of the cell cycle. This includes the CDK inhibitor, p27. In mice knocked down for Cks1, high levels of p27 accumulate (Spruck et al. 2001). Another level of post-translational regulation of p27 level is mediated by peptidyl-prolyl-isomerase PIN1. PIN1 binds specifically to its substrates at the serine/threonine-proline motifs when the serine or threonine residue is phosphorylated, and catalyzes isomerization of serine/threonine-proline peptide bond, resulting in conformational and functional changes of its substrate (Liou et al. 2011; Cheng et al. 2013). It has been shown that PIN1 binds p27 and induces conformational change that hinders the binding between p27 and CKS1 (Zhou et al. 2009). As a result, PIN1 positively regulates p27 level in competition with CKS1.

Apart from inhibiting cell-cycle entry, p27 is known to have cell-cycle-independent roles in controlling neuronal migration in the developing mouse neocortex. In particular, stabilization of p27 by the neuronal-specific CDK, CDK5, has been shown to be crucial in this context (Kawauchi et al. 2006). Studies on mitotic as well as neuronal cells have indicated that during migration, p27 mediates actin cytoskeleton reorganization through inhibition of RhoA, a small GTPase involved in the Rho/ROCK kinase signaling cascade (Besson et al. 2004). An important downstream effector of this pathway is coflin, which acts as an actin severer. LIM and other kinases have been shown to negatively regulate the activity of coflin by phosphorylation of the serine residue at amino-acid position 3 (Mizuno 2013). Precise control of coflin activity is important in cellular migration as well as in processes involving actin cytoskeleton remodeling, such as dendritic spine maturation (Pontrello and Ethell 2009; Tolias et al. 2011). Non-phosphorylated or activated coflin promotes the formation of coflin-actin rods or aggregates that are typically identified in neurons in neurodegenerative disorders such as Alzheimer’s disease (AD) (Huang et al. 2008).

In this study, we demonstrated that CKS1 possesses a cell-cycle independent role in controlling dendritic spine maturation. Through mediating p27 degradation, and thus RhoA activation, CKS1 negatively controls coflin activity. CKS1 is expressed strongly in the adult hippocampus. The sequelae of Cks1 deletion, hence coflin over-activation and formation of coflin-actin aggregates, include impaired maturation of hippocampal dendritic spines, an inability to establish late-phase long-term potentiation (LTP) and impaired hippocampal-based spatial learning.

### Materials and Methods

#### Animals

All experiments were conducted in 3–4-month-old male Cks1 knockout mice (Cks1−/−) (Frontini et al. 2012), and their wild type (WT) littermate controls. All procedures were conducted in accordance with the United Kingdom Animals (Scientific Procedures) Act, 1986 following institutional ethical approval at the University of Oxford and University of Sussex.

#### X-Gal Histochemistry

Mice were anesthetized with chloroform and fix-perfused transcardially with 4% paraformaldehyde in 0.1 M sodium phosphate-buffered saline (PBS). Brains were removed and incubated in cold fix for an additional 15 min. After rinsing 3 times in rinse buffer (100 mM sodium phosphate (pH 7.3), 2 mM MgCl2, 0.01% sodium deoxycholate, 0.02% Nonidet P40), sections were stained (rinse buffer plus 5 mM potassium ferrocyanide, 5 mM potassium ferricyanide, and 1 mg/ml 5-bromo-4-chloro-3-indolyl-beta-D-galactopyranoside) overnight at 4 °C. Sections were post-fixed before sectioning and mounting.

#### Novel Object Recognition

The Novel Object Recognition (NOR) task was performed in an open-field apparatus (40 cm wide × 60 cm long × 40 cm high) placed under a dim light. In the habituation phase, mice were individually allowed to explore the box for 10 min per day for 3 days. In the training trial, mice were presented with 2 identical, emotionally neutral plastic objects (such as a red cube), placed in opposite corners of the box and allowed to explore for 5 min. In the test trial performed 24 h later, we replaced one of the familiar object with a new one (e.g. yellow pyramid). Objects were similar in size and emotionally neutral, but varied in shape and color. Mice were allowed to explore for 5 min and exploratory behavior recorded, i.e. head orientation, sniffing, nose to object distance ≤1 cm. All trials were video-tracked using Ethovision XT 7.1 (Noldus Information Technology). We determined a preference index (PI), which is a difference in the new object exploration time divided by the total time spent exploring the 2 objects. The open-field box and objects were thoroughly cleaned with 70% ethanol solution, dried, and ventilated between tested mice to eliminate odor cues.
The Barnes maze test was used to assess spatial learning abilities. The maze consisted of a white, polypropylene disk of 100 cm diameter, mounted 50 cm above the floor. The disk had 20 holes of 5 cm diameter and evenly spaced around the periphery. A black acrylic drawer was located beneath one of the holes and served as the escape box. Fixed spatial cues were placed on the walls and a bright light (100 W) provided the aversive stimuli. The method was modified from Patil et al. (2009). For each trial, mice were allowed to freely explore the maze for 2 min or until reaching the escape box, where they would remain for 1 min before being returned to their home cage. If a mouse failed to find the escape box within 2 min, the experimenter would gently direct the animal to the escape box where it would remain for 1 min. During 5 consecutive days, mice had either 3 trials per day (with a retention time of 15 min) or 1 trial per day (retention time of 24 h). The time spent before finding the escape box was measured as an indication of spatial learning. All trials were video-tracked using Ethovision XT 7.1 (Noldus Information Technology), which recorded distance traveled and latency to find the escape box. The maze and escape box were cleaned carefully with a 70% ethanol solution between each trial to eliminate odor cues.

Electrophysiology

Mice were anesthetized with pentobarbitone prior to decapitation and preparation of slices. Transversal hippocampal slices (350 μm) were cut with a Microm HM650V slicer in ice-cold artificial cerebrospinal fluid (aCSF) comprising (in mM): 119 NaCl, 2.5 KCl, 2.5 CaCl2, 1.3 MgSO4, 1.25 NaH2PO4, 25 NaHCO3, 11 glucose (pH 7.2–7.4, equilibrated with 95% O2/5% CO2), stored at 20–24 °C for at least 1 h, then transferred to a submerged recording chamber perfused with aCSF at 32 °C for at least 30 min before recording. An extracellular concentric tungsten stimulation electrode was positioned in the CA1 stratum radiatum. A cut was made between the CA3 and CA1 areas to prevent polysynaptic activity. Single-shock stimuli were applied at 15 s interval, and field potential EPSPs (fEPSPs) were recorded in the CA1 stratum radiatum using glass capillary electrodes (5–10 MΩ) filled with aCSF. Stimulation intensity was set to 50% of maximal fEPSP amplitude. Theta-burst stimulation (TBS) comprised 10 trains of 5 pulses each at 100 Hz with 200 ms inter-train interval. Theta-burst stimulation (TBS) was analyzed and magnitude of LTP was defined as % of baseline. Miniature EPSCs (mEPSCs) were recorded from CA1 neurons with 5–10 MΩ filled with aCSF. mEPSCs were analyzed from at least 5 min recording episodes, with stable access resistance (<25 MΩ). Data were low-pass filtered (4–5 kHz) and acquired at 10–20 kHz for off-line analysis. The GABAAR blocker picrotoxin (100 μM) and tetrodotoxin (TTX) (1 μM) were present in all mEPSC experiments. Data were analyzed using pClamp 10 (Axon Instruments).

Dendritic Spine Density and Structure Analysis

Slices were fixed with 4% PFA and 0.2% picric acid solution overnight at 4 °C, and then washed in 0.1 M phosphate buffer. Neurobiotin was visualized by incubating with Alexa Fluor 488-conjugated streptavidin (Invitrogen, UK; diluted 1:1000) in TBS with 0.3% Triton X-100. Slices were mounted in Vectashield (Vector Laboratories). Fluorescent images of dendrites were collected using a confocal laser scanning microscope (Leica TCS SP5). At least 3 randomly selected areas with 50–70 μm length each were imaged from a single pyramidal cell. About 3 or more cells were analyzed from each animal and having at least 3 animals per genotype. Dendritic spines morphology was analyzed using the NeuroStudio software (Rodriguez et al. 2008).

siRNA Transfection

Specific siRNA targeting Cks1 (siCks1) and control siRNA (siCtrl) were purchased from Dharmacon (SMARTpools) and the cells were transfected with Oligofectamine transfection reagent (Life-Technologies-Invitrogen) following the manufacturer’s instructions. Cells were analyzed 48 h after transfection.

Real-Time PCR and Gene Expression Analysis

mRNA of the hippocampus tissues was extracted by TRIzol reagent (Life Technologies) and cDNA was reverse transcribed using SuperScript III Reverse Transcriptase (Life Technologies). Power SYBR Green PCR Master Mix (Applied Biosystems, Life Technologies) was used for Real-time PCR. Transcript expression is presented as average Ct. Primer sequences for Cks1 mRNA were TACGAGGACGGAGGTCCGAAT (Forward) and ACCAGCTTGCTATGTCCTTGGG (Reverse). The fold changes for Cks1 transcript from hippocampus of WT mouse relative to that of Cks1−/− mice was calculated with the 2−ΔΔCt method (Huggett et al. 2005).

Immunoprecipitation and Western Blotting

Hippocampal extracts were made from homogenized Cks1−/− and WT brains in lysis buffer containing 5 mM HEPES (pH 7.3), 200 mM NaCl, 1.5 mM MgCl2, 0.2 mM EDTA, 20 mM β-glycerophosphate, 1 mM sodium orthovanadate, 0.5% Triton X-100, and 5% glycerol with protease inhibitors (Roche). Primary hippocampal neurons were made from E14 embryos (see below). Anti-p27 antibody (#528, Santa Cruz Biotechnology) was firstly cross-linked to Protein A/G agarose beads (Thermofisher) using dimethyl pimelimidate dihydrochloride (Sigma). Extracts were incubated with antibody-conjugated beads at 4 °C overnight. After extensive washing, the immunoprecipitates were separated by SDS-PAGE for Western blot analysis with anti-p27 antibody (#610241, BD Transduction Laboratories) and anti-RhoA antibody (#sc-418, Santa Cruz Biotechnology). For active RhoA pull-down, a GSTRhotekin-RBD column was used according to the manufacturer’s protocol (#16116, Thermofisher). Cofilin was detected using the following antibodies: anti-cofilin (#5175, Cell Signaling), anti-Ser3 cofilin (#3313, Cell Signaling).

Culture of Primary Hippocampal Neurons and Immunostaining

The primary hippocampal neurons were derived from the E14 embryos of WT and Cks1−/− mice. The neurons were seeded on 24-well plates with coverslips coated with poly-L-lysine with Neurobasal Medium (Life Technologies) and B27 supplement (50×). Immunostaining was then performed on the primary neurons after culture for 14 days. For neurons immunostaining, cells were rinsed with PBS twice and fixed for 30 min in a solution of 4% paraformaldehyde, pH 7.4. Coverslips were then rinsed 3 times in PBS and permeabiled with ice-cold methanol for 90s. Permeabilization solution was removed and washed 3 times with PBS. Anti-cofilin antibody (#5175, Cell Signaling) and anti-beta III tubulin antibody [TUJ-1] (ab14545, Abcam)
were added together with a donkey serum blocking solution in PBS and set to incubate overnight at 4 °C. Coverslips were then rinsed 3 times in PBS for 10 min. Samples were further incubated for 1 h in anti-rabbit Alexa Fluor 488-conjugated secondary antibodies and anti-mouse Alexa Fluor 647-conjugated secondary antibodies (Invitrogen). The slips were washed finally with PBS for 3 times. Images were taken with Carl Zeiss LSM 510 Meta/Axiocam. Cofilin aggregations were counted with ImageJ software with puncta analyzer plug-in (National Institutes of Health). Details of the quantification method using this plug-in have been described previously, and each of the image backgrounds was subtracted (rolling ball radius = 50) in order to detect discrete puncta (cofilin aggregates) without introducing background noise (Ippolito and Eroglu 2010).

Statistical Tests and Analyses
Significance was analyzed either with the Mann–Whitney test or t-test, and for the multiple parameter comparisons with 1-way ANOVA and post hoc Bonferroni or Tukey’s test. Parametric distribution of data was tested with Shapiro–Wilk test.

Results
CKS1 is Involved in Establishment of Long-Term Memory in Adult Hippocampus
During investigation of CKS1 in the developing murine cortex, we recently observed that apart from controlling cell-cycle exit during neurogenesis, CKS1 was also actively expressed in mature neurons (Frontini et al. 2012). We therefore examined Cks1 expression in the adult brain by using β-galactosidase activity as a marker in heterozygous mice where one copy of Cks1 was disrupted by a LacZ insertion cassette. Cks1 expression was detected in various regions of the brain (Fig. 1A), including the hippocampus (Fig. 1B). Adult hippocampal expression of Cks1 was further confirmed with quantitative real-time PCR (RT-PCR) of RNA extracted from the hippocampi of WT mice (Fig. 1C). Given the well-established role of CKS1 in dividing cells, we expected to see Cks1 expression in areas where adult neurogenesis occurs (Drew et al. 2013), but not in post-mitotic neurons. Surprisingly, in addition to the dentate gyrus, Cks1 expression was detected in the CA1, CA2 and CA3 areas and particularly in the stratum pyramidale.

To determine whether the Cks1 expression has significance in brain function, we compared the behavior of Cks1 knockout (Cks1−/−) mice with WT littermates. Although Cks1−/− mice were physically smaller than WT mice, possibly related to the accumulation of p27 (Spruck et al. 2001), they did not show statistically different performance on the standardized SHIRPA protocol (Supplementary Table S1), and no motor deficits were observed.

Given the prominent Cks1 expression in the adult hippocampus, we tested Cks1−/− mice and their WT littermate controls in a NOR task. Cks1−/− mice displayed a statistically significant (P < 0.05) decrease in preference for a novel object (Fig. 2A). To further investigate if this was due to a hippocampal defect, hippocampus-dependent spatial learning and memory were examined using Barnes circular maze (Patil et al. 2009). Performance was measured by the time (primary latency) and distance (primary path length) taken for an animal to reach an escape hole from the open surface of a Barnes maze arena. Mice were initially given 3 learning trials, 15 min apart every day for 4 days. After 12 test trials, animals were tested on the fifth day to see whether they remembered the route to the escape hole without further training. If acquisition of new memory was normal, Cks1−/− mice and their WT control animals would be expected to demonstrate a similar degree of reduction in latency. However, the Cks1−/− mice spent a significantly longer time (P < 0.01, t-test) and used a longer path, very close level of significant difference the WT (P = 0.05), to reach the escape hole, reflecting a defect in establishing long-lasting memory (n = 18 mice in both groups) (Fig. 2B). We next performed the Barnes maze experiment on a separate cohort of mice, but providing the mice 1 trial per day for 6 days (i.e. a retention time of 24 h) instead of 3 temporarily closely spaced trials each day (i.e. a retention time of 8 h)
of 15 min each). Similarly, Cks1−/− mice exhibited a significant impairment in memory as reflected by the longer primary latency and longer primary path length taken by them to reach the escape hole on days 4–6 and 5–6, respectively (P < 0.05 for both, t-test), compared with WT littermates (Fig. 2C). To support the contention that WT mice and Cks1−/− mutants are distinct in their learning ability and not their performance in the Barnes maze per se, we tested an independent group of mice in the Barnes maze. Our results confirmed that WT mice (n = 6) and Cks1−/− mutants (n = 6) have no performance difference the first time they encounter the maze (primary latency, \( P = 0.64 \); primary path length \( P = 0.70 \)). Collectively, our results highly suggested that CKS1 in the adult hippocampus is required for normal acquisition and consolidation of memory.

**CKS1 is Required for Late LTP and Dendritic Spine Maturation**

We suspected Cks1−/− mice would have difficulties to establish LTP, which is considered to be the cellular substrate of hippocampal memory formation (Bliss and Collingridge 1993). Studying field excitatory postsynaptic potential (fEPSP) in acute hippocampal slices, we observed that both WT and Cks1−/− mice establishing early (<60 min from TBS, post-TBS) LTP (Fig. 3A1, A2). The recordings were made with standard extracellular solution without added drugs. At 60 min post-TBS, the fEPSP potentiation was significant from baseline (15 min) in the WT mice hippocampal Schaffer collateral pathway (1.38 ± 0.08, \( n = 14, P < 0.01 \)) as well as in the Cks1−/− (1.26 ± 0.05, \( n = 15, P < 0.01 \)) (at 50–60 min from TBS). Although average early LTP was moderately smaller in the Cks1−/− mice, there was significant difference between the 2 genotypes (\( P = 0.18, t\)-test).

In recordings following the fEPSP for 2 h post-TBS, we found that late LTP was compromised in Cks1−/− mice (1.10 ± 0.03, \( n = 6 \)) as compared with the littermate controls (1.65 ± 0.14, \( n = 6 \)) (Fig. 3A2) (\( P < 0.01 \) comparing baseline-normalized fEPSPs between the groups at 110–120 min post-TBS, \( n = 6 \) and 6, t-test). Thus, the inability of Cks1−/− mice to establish late LTP may at least partially explain the memory defects we observed on the NOR experiment and the Barnes maze.

![Image](memory.png)
presence of tetrodotoxin, 1 μM and the GABA<sub>A</sub>R blocker, picrotoxin, 100 μM (Fig. 3B1, B2). Pyramidal cells in Cks1<sup>−/−</sup> mice showed significantly lower mEPSC frequency (0.39 Hz, n = 12) than those of WT littermates (1.04 Hz, n = 11) (P < 0.01, t-test) (Fig. 3B2). In addition, we found that mEPSC amplitudes were moderately higher in the Cks1<sup>−/−</sup> mice (13.8 ± 0.5 pA) than in control cells (11.5 ± 0.6 pA, P < 0.01, t-test). These findings suggest that hippocampal CA1 pyramidal cells in the Cks1<sup>−/−</sup> mice have lowered density of afferent glutamatergic synapses and the average strength of a quantal current is moderately stronger than in the WT hippocampus.

During learning, neuronal activity is known to facilitate the growth of dendritic spines that results in an increase in spine head area-to-length ratio (hence formation of the so-called mushroom spines from filopodia or thin spines). This type of structural plasticity is commonly associated with establishment of late LTP (Bosch and Hayashi 2012). Hence, we studied whether dendritic spine maturation differed between Cks1<sup>−/−</sup> and WT mice. We visualized and analyzed dendrites of pyramidal cells (which we previously made electrophysiological recordings from and filled them with neurobiotin) in the hippocampal CA1 area with confocal microscopy. We found that Cks1<sup>−/−</sup> pyramidal cell apical dendrites were deficient in mushroom spines, which represent the mature spine form (Fig. 3C1). The relative proportion of mushroom spines in dendrites was significantly lower in Cks1<sup>−/−</sup> pyramidal cells (21 ± 4%, n = 8, P < 0.01) than in WT pyramidal cells (38.6 ± 6%) (Fig. 3C2). Moreover, to assess the presence of dendritic synapses, we examined the expression levels of synaptophysin and PSD95 (pre-synaptic and postsynaptic markers, respectively) in the primary hippocampal neurons from E14 embryo of the Cks1<sup>−/−</sup> and the WT mice using immunoblotting. As shown in Figure 3D1, D2, the expression levels of synaptophysin and PSD95 were significantly lower in the Cks1<sup>−/−</sup> neurons, suggesting that fewer synapses were present in the Cks1 null neuronal dendrites. All these results supported the notion that CKS1 contributes to formation of dendritic spines and in its absence, the establishment of late LTP and long-term memory, development of mushroom-shape spines and functional dendritic synapses are compromised.

**CKS1 Controls Phosphorylation of Cofilin Through Destabilization of p27 and Activation of RhoA Kinase**

Dendritic spine maturation requires active actin cytoskeleton remodeling (Calabrese et al. 2006). Cofilin, an actin cytoskeleton severer, is essential in this process. Previous studies have shown that expression of a constitutively active non-phosphorylatable cofilin inhibited dendritic spine maturation (Shi et al. 2009). To examine whether the inactive phospho-Ser3 form of cofilin in hippocampal extract of Cks1<sup>−/−</sup> mice was reduced, an antibody that specifically recognizes the phospho-Ser3 form of cofilin was used. Immunoblotting showed that phospho-Ser3 cofilin was significantly reduced in hippocampus of Cks1<sup>−/−</sup> mice (Fig. 4A1–A3). Similarly, the level of phospho-Ser3 cofilin was also markedly lower in Cks1<sup>−/−</sup> primary hippocampal neurons than that of the WT (Fig. 4A4–A6). Because previous studies have shown that non-phosphorylated cofilin aggregation induces synaptic loss in hippocampal neurons (Cichon et al. 2012), we investigated if there was also increased cofilin aggregation in Cks1<sup>−/−</sup> primary hippocampal neurons (Fig. 4B1, B2). The percentage of Cks1<sup>−/−</sup> primary hippocampal neurons with cofilin aggregates (59.47 ± 2.58%, n > 200) was significantly higher (P < 0.0001) than that in WT neurons (11.33 ± 2.25%, n = 200).
Figure 4. CKS1 controls the phosphorylation of coflin at Ser3 site and the formation of coflin aggregates by limiting binding of p27 to RhoA in primary hippocampal neurons. (A) The level of coflin phosphorylated at Ser3 both in Cks1-/− hippocampal extracts and in primary hippocampal cells was lower than that in the WT hippocampal controls. (A1) Western blot of hippocampal extract using β-actin as loading control. (A2) Histogram showing relative intensity of total coflin in hippocampal extracts. Data were expressed as mean ± SEM (n = 9). (A3) Histogram showing relative amount of p-coflin (Ser3) in hippocampal extract. Data were expressed as mean ± SEM (n = 9). (A4) Western blot of primary hippocampal neurons with β-actin as loading control. (A5) Histogram showing relative intensity of total coflin in primary hippocampal neurons. Data were expressed as mean ± SEM (n = 9). (A6) Relative amount of p-coflin (Ser3) in primary hippocampal neurons. Data were expressed as mean ± SEM (n = 9). (B) The percentage of primary hippocampal neurons with aggregates was significantly higher in the Cks1-/− genotype than in WT derived neurons. (B1) Confocal immunofluorescence images illustrate aggregates in WT and Cks1-/− neurons. Scale 50 μm. (B2) Histogram showing % of cells associated with the aggregates. (C) Increased amount of RhoA bound to p27 in Cks1-/− cells; (C1, C2) Immunoprecipitation of p27 showed that more RhoA was bound to p27 in Cks1-/− primary hippocampal neurons than in the WT. (C3) Histogram showing amount of RhoA interacting with p27 in primary hippocampal neurons. Data were expressed as mean ± SEM (n = 9). (D) A GST-rhotekin column was used to pull-down active RhoA in WT or Cks1-/− primary hippocampal neurons. (D1) By using antibody specific to RhoA, more active RhoA was detected in WT primary hippocampal neurons than in Cks1-/− mice cells. Input showed the same amount of total RhoA used in the RhoA pull-down assay for WT and Cks1-/−. (D2) Histograms showing the amount of active RhoA in primary hippocampal neurons. Data were expressed as mean ± SEM (n = 9).
Neuron-specific class III β-tubulin, a neural specific marker, was used to outline the normal neuronal morphology.

Ser3 phosphorylation of coflin is mediated by GTPase RhoA, which is in turn negatively regulated by p27 (Kawauchi et al. 2006; Belletti et al. 2010). Given that Cks1−/− mice accumulate

\( n > 200 \) (Fig. 4B2). Figure 5. Cks1 knocked down in WT primary hippocampal neurons leads to increased coflin aggregates. WT primary hippocampal neurons were treated with either scrambled control siRNA (siCrtl) or siRNA against Cks1 (siCks1). The effects of Cks1 on p27, RhoA and coflin were examined with immunoblotting. The results of these experiments were similar to the results observed in Cks1−/− primary hippocampal neurons. (A) The expression of CKS1 in WT primary hippocampal neurons was down-regulated by siCks1, resulting in decreased p-cof in neurons treated with siCtrl compared to siCks1. (B1) Western blot of using β-actin as loading control. (B2-A4) Histograms showing relative intensity of CKS1, coflin, and p-cof (Ser3) in primary neuron extracts. Data were expressed as mean ± SEM (n = 9). (B) Immunoprecipitation of p27 showed that more RhoA was bound to p27 in the cells treated with siCks1. (B1, B2) Western blot with β-actin as loading control. (B3) Histograms showing amount of RhoA interacting with p27 in primary neuron extract. Data were expressed as mean ± SEM (n = 9). (C) From active RhoA pull-down, more active RhoA was present in the primary hippocampal neurons treated with siCrtl. (C1) Western blot showing active and total RhoA. (C2) Histograms showing relative intensity of active RhoA in primary neuron extracts. Data were expressed as mean ± SEM (n = 9). (D) WT primary hippocampal neurons treated with siCrtl or siCks1. Confocal fluorescence micrographs showing DAPI and immunohistochemical reaction against coflin and tubulin. Scale 50 μm. (E) The percentage of coflin aggregates was significantly higher in the neurons treated with siCks1 than siCrtl (t-test). Scale 50 μm.
high levels of p27, we hypothesized that RhoA was inhibited due to increased RhoA bound to p27, resulting in decreased cofilin phosphorylation in the brain of Cks1−/− mice. To test this, we examined RhoA binding to p27 in primary hippocampal neurons of WT and Cks1−/− mice. Immunoprecipitation experiments showed increased amount of RhoA bound to p27 in the Cks1−/− background (Fig. 4C1–C3). To confirm if the increased binding to p27 resulted in suppression of RhoA activity in Cks1−/− mice, we employed a Rhotekin Rho binding-domain column to enrich for active GTP-bound Rho kinases. We found that Cks1−/− primary hippocampal neurons indeed harbored less active RhoA than the WT littermate controls (Fig. 4D1–D7). To further validate the effect of CKS1 on p27-RhoA axis, Cks1 was knocked down with siRNA in primary hippocampal neurons from WT mice (Fig. 5).
Consistent with the findings in Cks1−/− mice, knocking down Cks1 in WT neurons resulted in reduced amount of CKS1 (Fig. 5A), increased p27 level and p27-RhoA binding (Fig. 5B1–B3), inhibition of RhoA (Fig. 5C1, C2), and increase in the formation of coflin aggregates (Fig. 5D, E). Taken together, these findings suggested that CKS1 is required for Ser3 phosphorylation of coflin and for preventing coflin aggregates formation.

**Decreasing p27 Level by PIN1 Inactivation Reduces Coflin Aggregate Formation in Cks1−/− Hippocampal Neurons**

Coflin aggregation and rod-like aggregate formation are associated with the development of neurodegenerative diseases, such as AD (Bamburg et al. 2010). The rods have been shown to
be co-localized with phosphorylated tau and responsible for phosphorylated tau accumulation in striated neuropil threads (Whitteman et al. 2009, 2011), a characteristic of tau pathology in the early stage of AD brain. The peptidyl-prolyl-isomerase PIN1 has been shown to compete with CKS1 for interaction with p27 and suppression of PIN1 activity is associated with destabilization of p27 (Zhou et al. 2009). As shown in Figure 6A, the coflin aggregates gradually disappeared with treatment of increasing concentration of PiB, an inhibitor of PIN1, in primary hippocampal neurons from Cks1−/− mice. PiB treatment reduced the p27 level, decreased the interaction between p27 and RhoA, and increased phosphorylation of coflin (Fig. 6B1–B7). Similarly, in WT primary hippocampal neurons with Cks1 knocked down by siRNA, PiB treatment also resulted in diminished number of coflin aggregates (Fig. 6C). In addition, it decreased binding between p27 and RhoA, and increased phosphorylation of coflin (Fig. 6D1–D7). Treatment with PINTIDE, a very specific PIN1 inhibitory phosphopeptide, also showed similar biochemical results, confirming the effect of PIN1 inhibition in reversing the coflin aggregates formation (Fig. 7A–C). Taken together, the results suggested that regulation of p27 level via PIN1 and CKS1 determines the activity of coflin and the formation of coflin aggregates.

Discussion

CKS proteins are generally regarded as cell-cycle regulators. Although CKS1 does not bind the brain specific CDK, CDK5 directly (Pines 1996), it may bind indirectly as a complex in the brain (Veeranna et al. 2000). Here we describe a post-mitotic role for CKS1 in facilitating dendritic spine maturation in the hippocampus. We showed that CKS1 is actively expressed in the adult brain. Cks1−/− mice exhibit impaired learning of hippocampus-dependent tasks, implying that CKS1 is required for the establishment of memory. Indeed, electrophysiological studies showed that the absence of CKS1 seriously compromised establishment of LTP.

In our model, we ascribe the phenotypes we saw in the Cks1−/− mice to decreased RhoA kinase activity due to increased binding to p27. In order to establish long-lasting LTP, inactivation of coflin by Rho kinase-mediated phosphorylation is required to increase F-actin content within dendritic spines (Fukazawa et al. 2003). RhoA, through its effector RhoA kinase ROCK, activates LIM kinase (LIMK) that in turn phosphorylates coflin (Maekawa et al. 1999). Accordingly, a number of chemical agents, which interfere with actin polymerization, specifically block late LTP (Rex et al. 2009). In the context of the hippocampus, we postulate that Cks1−/− partially phenocopies the S3A coflin mutant. The coflin S3A mutant is nonphosphorylatable on serine 3, hence resistant to inhibitory phosphorylation. Over-expression of the S3A mutant results in an increase in the active form of coflin and an inability to mature dendritic spines to the mushroom form. Also, elevated coflin activity under certain conditions has been shown to contribute to enhanced AMPA receptor trafficking during synaptic potentiation (Gu et al. 2010). This may explain the increased amplitude seen in the Cks1−/− background. Of note, coflin phosphorylation is decreased, but not absent in the Cks1−/− mouse. This is expected, as coflin phosphorylation is under control of multiple signaling pathways (Pontrello and Ethell 2009). A study has showed that p27 promotes microtubule polymerization and negatively regulates myosin II activity (Godin et al. 2012). Inhibition of myosin IIb has been shown to destabilize mushroom spines and inhibit excitatory synaptic transmission (Ryu et al. 2006; Koskinen et al. 2014). Further investigation is required to see whether this also contributes to the Cks1−/− phenotype.

The implication of CKS1 in memory formation is manifold. First, this suggests an evolution redundancy in the use of cellular mechanisms that control cytoskeleton remodeling within and without the mitotic cycle. Secondly, this implies that when neurons exit the mitotic cycle, certain components of the cell-cycle machinery remain, but take on different roles. Cyclin E has been shown to play a similar role in post-mitotic neurons (Odajima et al. 2011). Our work therefore adds to the increasing repertoire of cell-cycle proteins that play non-cell-cycle dependent roles in neurons and in neurodegeneration (van Leeuwen and Hoozemans 2015).

In summary, our results on this Cks1−/− murine model demonstrate that CKS1 has a cell-cycle independent role in adult hippocampus contributing to memory consolidation, pyramidal cell dendritic spine maturation and late LTP. Inhibition of CKS1 facilitates formation of coflin aggregates through the p27-RhoA axis (Fig. 8), yet, the exact role of CKS1 in the pathogenesis of human neurodegenerative diseases remains to be determined.
Figure 8. Cks1-mediated control of RhoA and coflin phosphorylation via p27. Cks1, via regulating p27 ubiquitylation and degradation, fine tunes RhoA activity, and hence coflin phosphorylation during this process. In the absence of Cks1, p27 level is increased. As a result, there is less active RhoA and decreased coflin phosphorylation, leading to formation of coflin aggregation and impairment of dendritic spine maturation.

Authors’ Contributions
Y.M.N. performed the in vitro and primary neuronal cell culture experiments, and microscopy. A.K. and K.L. performed the histology and electrophysiology study, and analyzed the data. L.J., A.S., S.E.W., D.N.S., and A.M.C. performed the mouse behavior studies and analyzed the data. S.L., A.M., D.D., W.G., and P.W.H., provided technical support. Y.M.N., E.T. and V.Y. wrote the manuscript. A.M.C., K.L., E.T., and V.Y. supervised the project.

Funding
This work was supported by funding from the Wellcome Trust (to V.Y., K.L.), Medical Research Council (to S.E.W. and D.N.S.: G1000008; A.M.C. and A.S.: G0600223, G1100074; K.L., V.Y.), Academy of Medical Sciences (to V.Y.), British Heart Foundation (to V.Y.) and The University of Hong Kong (to E.T. and Y.M.N.). V.Y. is supported by a fellowship from the National Institute for Health Research at Guy’s and St. Thomas’ NHS Foundation Trust in partnership with King’s College London. E.T. is a recipient of the Outstanding Young Researcher Award 2010, The University of Hong Kong.
