(Received 8 July 2017; published 17 November 2017)

Tests of lepton-universality as rate ratios in $b \to s\ell\ell$ transitions can be predicted very accurately in the Standard Model. The deficits with respect to expectations reported by the LHCb experiment in muon-to-electron ratios of the $B \to K^{(*)}\ell\ell$ decay rates thus point to genuine manifestations of lepton nonuniversal new physics. In this paper, we analyze these measurements in the context of effective field theory. First, we discuss the interplay of the different operators in $R_K$ and $R_{K^*}$ and provide predictions for $R_{K^*}$ in the Standard Model and in new-physics scenarios that can explain $R_K$. We also provide approximate numerical formulas for these observables in bins of interest as functions of the relevant Wilson coefficients. Secondly, we perform frequentist fits to $R_K$ and $R_{K^*}$. The Standard Model disagrees with these measurements at $3.7\sigma$ significance. We find excellent fits in scenarios with combinations of $O_{Q(10)}^\ell = s^\mu b^\ell c^\ell f_{\rho}(y_{5})$ operators, with pulls relative to the Standard Model in the region of $4\sigma$. An important conclusion of our analysis is that a lepton-specific contribution to $O_{Q(10)}$ is important to understand the data. Under the hypothesis that new-physics couples selectively to the muons, we also present fits to other $b \to s\ell\ell$ data with a conservative error assessment and comment on more general scenarios. Finally, we discuss new lepton universality ratios that, if new physics is the origin of the observed discrepancy, should contribute to the statistically significant discovery of new physics in the near future.

DOI: 10.1103/PhysRevD.96.093006

I. INTRODUCTION

Ratios of decay rates such as $B \to K^{(*)}\ell\ell$ for different leptons $\ell = e$ or $\mu$ are protected from hadronic uncertainties and can be very accurately predicted in the Standard Model (SM) [1,2]. Therefore, significant discrepancies with experiment in these observables would have to be interpreted as unambiguous signals of new physics (NP) that, in addition, must be related to new lepton nonuniversal interactions. After first measurements reporting no significant deviation from universality (within large experimental uncertainties) at $B$-factories [3–5], in 2014 the LHCb Collaboration reported a quite precise measurement of the ratio $R_K = \Gamma(B \to K\mu\mu)/\Gamma(B \to K\ell\ell)$ [6]

$$R_K = 0.745^{+0.090}_{-0.074} \pm 0.036,$$

in the bin corresponding to dilepton mass squared $q^2 \in [1, 6]$ GeV$^2$ that deviated from the SM predictions $R_K = 1.0004(8)$ [1,2] with a significance of $2.6\sigma$. Recently, the LHCb reported the measurement of $R_{K^*} = \Gamma(B \to K^*\mu\mu)/\Gamma(B \to K^*\ell\ell)$ in two bins of $q^2$ [7],

$$R_{K^*[0.045,1.1]} \text{ GeV}^2 = 0.660^{+0.110}_{-0.070} \pm 0.024,$$
$$R_{K^*[1.1,6]} \text{ GeV}^2 = 0.685^{+0.113}_{-0.069} \pm 0.047,$$

where the first error is statistical, the second systematic, and which show again deficits with respect to the SM predictions (see below),

$$R_{K^*[0.045,1.1]}^{SM} \text{ GeV}^2 = 0.920(7),$$
$$R_{K^*[1.1,6]}^{SM} \text{ GeV}^2 = 0.996(2),$$

with a significance of $2.3\sigma$ and $2.4\sigma$, respectively.
In addition, during the last few years there have been considerable investigations related to tensions with SM predictions in the angular analysis of \( B \to K^\pm \mu^\mp \mu^\pm \mu^\mp \) and branching fractions \([13-15]\) whose significance have been claimed to be in the 4–5\( \sigma \) range in some global analyses \([16-18]\), although these observables are afflicted by hadronic uncertainties that obscure the interpretation and significance of the anomaly \([19-36]\). On the other hand, if the NP coupled selectively to the muons, then the effect that would be needed to explain the \( R_K \) anomaly could also naturally explain these other anomalies in the angular distributions and rates \([37-40]\). Several authors have proposed combinations of the angular observables of \( B \to K^{(*)}\ell^+\ell^- \) for muons and electrons probing lepton universality, that are again protected from hadronic uncertainties and sensitive to specific scenarios of NP \([29,41-43]\). Indeed, some of these observables have been recently analyzed by the Belle \([10]\) Collaboration showing overall consistency with the SM, albeit with large experimental errors.

In this paper, we perform an analysis of the \( R_K \), measurements together with \( R_{K^*} \) and other \( b \to s\mu\mu \) data. First, we describe the dependence of the relevant lepton-universality ratios on lepton-specific Wilson coefficients of the weak Hamiltonian of \( b \to s\ell^+\ell^- \) transitions, focusing in the correlations induced between \( R_K \) and \( R_{K^*} \). We then present numerical predictions for \( R_K \) and \( R_{K^*} \) in the SM and in benchmarks scenarios of NP for the bins of interest and present numerical formulas for their dependence on the Wilson coefficients. Finally, we present a series of fits to the data, including in subsequent steps the \( B_s \to \mu^+\mu^- \) branching fraction and all the measurements of \( CP \)-averaged combinations of angular observables of \( B \to K^{(*)}\ell^+\ell^- \) at low \( q^2 \).

We describe our findings in terms of frequentist statistic inference and discuss the robustness of the results to variations of hadronic uncertainties.

II. STRUCTURE OF THE NEW-PHYSICS CONTRIBUTIONS TO \( R_{K^{(*)}} \)

To leading order in \( G_F \) the effective Hamiltonian for \( b \to s\ell^+\ell^- \) transitions at low-energies (\( \mu \sim m_b \)) in the SM is \([44-46]\)

\[
\frac{d^{\nu} \Gamma_{K}^{\nu}}{d q^2} = N_{K}^3 |k|^3 f_{+}(q^2)^2 \left( |C_{10}^{e} + C_{10}^{\mu s}|^2 + |C_{0}^{e} + C_{0}^{\mu s}|^2 + 2 \frac{m_B}{m_K} C_{7} f_{+}(q^2)^2 - 8 \mathcal{A}^2 \right) \]

where \( \mathcal{A} \equiv \Lambda_{QCD} \) is a dimensionful normalization constant that drops out in the ratio \( R_K \), \( f_{+}(q^2) \) are form factors, and \( h_K \) encompasses the

\[
\mathcal{H}_{\text{eff}}^{\mu} = \frac{4G_F}{\sqrt{2}} \sum_{p=u,c} \lambda_p \left( C_1 O_1^p + C_2 O_2^p + \sum_{i=3}^{10} C_i O_i \right),
\]

with \( \lambda_p = V_{pb} V_{ps}^* \). The \( \mathcal{O}_7 \) and \( \mathcal{O}_{9,10} \) are the electromagnetic penguin and the semileptonic operators, respectively, and \( \mathcal{O}_{1,2}, \mathcal{O}_{3,6} \), and \( \mathcal{O}_8 \) are the “current-current”, “QCD-penguins” and “chromomagnetic” operators, respectively, which require of an electromagnetic interaction to contribute to the \( b \to s\ell^+\ell^- \) transition via “nonfactorizable” corrections, in the language of QCD factorization \([19]\). The effects of new physics beyond the SM can be modeled by modifying the Wilson coefficients \( C_1,...,C_{10} \) and by supplementing the effective Hamiltonian with chirally flipped \([b_{L(R)} \to b_{R(L)}] \) versions of these operators \( \mathcal{O}_7,..,10 \), and also four scalar and two tensor operators \([47]\).

Among all the possible operators present in \( \mathcal{H}_{\text{eff}} \), only the semileptonic ones,

\[
\begin{align*}
\mathcal{O}_7^{(s)} &= \frac{\alpha_{em}}{4\pi} (\bar{\psi}_s \gamma^\mu P_{L(R)}^s b)(\bar{\ell} \gamma_\mu \ell), \\
\mathcal{O}_{10}^{(s)} &= \frac{\alpha_{em}}{4\pi} (\bar{\psi}_s \gamma^\mu P_{L(R)}^s b)(\bar{\ell} \gamma_\mu \gamma_5 \ell).
\end{align*}
\]

can explain the deficit observed in \( R_K \). The current-current, QCD penguin and magnetic operators do not induce lepton-universality violation (LUV) because they connect to the dilepton pair through a photon. Scalar and tensor Lorentz structures cannot explain \( R_K \) either if they stem from an UV completion of the SM manifesting at the electroweak scale as \( SU(3)_c \times SU(2)_L \times U(1)_Y \)-invariant effective operators: Tensor operators with the particle content of the SM of the type \( \langle \bar{Q}_L \sigma_{\mu\nu} d_R \rangle \langle \bar{L}_L \sigma^{\mu\nu} \ell_L \rangle \) are forbidden by conservation of hypercharge, whereas \( \langle \bar{Q}_L \sigma_{\mu\nu} d_R \rangle \langle \bar{L}_L \sigma^{\mu\nu} \ell_L \rangle \) is identically equal to zero. On the other hand, out of the four possible scalar operators at low energies only two are independent, and these are found to be severely constrained by the \( B_q \to \ell\ell \) decay rates so they cannot explain \( R_K \) either (see Refs. \([37,38]\) for details).

In terms of the operators of the type \((5)\), and expanding around the massless limit for the lepton the differential decay rate of the \( B \to K\ell\ell \) process is \([47]\)
hadronic effects of the current-current, chromomagnetic and QCD penguin operators. It is clear from this equation that phase-space effects induced by the electron and muon masses are negligible as soon as $q^2 \gtrsim 1 \text{ GeV}^2$ and that the ratio of decay rates into muons and electrons must be very accurately equal to 1 (up to electromagnetic corrections [2]), and regardless of hadronic contributions since these are necessarily lepton-universal. Since, $C_{1,\ldots,8}$ do not directly result in LUV, any significant deficit from 1 in $R_K$ must be then caused by nonuniversal NP contributions $\delta C_{9,10}^{(\nu)}$. Hence, taking into account that $C_{9}^{SM}(m_b) = -C_{10}^{SM} = 4.27$, explaining the central value of the LHCb measurement in Eq. (1) with muon-specific NP contributions would require [37,38]

$$\delta C_{9}^{(\nu)} = -1, \text{ or } \delta C_{10}^{(\nu)} = +1,$$

or a suitable combination of the two in the leptonic left-handed combination.

$$\frac{d\Gamma_0}{dq^2} = N_{K^0} |k|_3 V_0(q^2)^2 \left( |C_9' - C_{10}'|^2 + \left| C_9' - C_{10}' + \frac{2m_b}{m_B} C_7 T_0(q^2) - 8\pi^2 h_{K^0} |^2 \right) + O\left( \frac{m_B^2}{q^2} \right), \right. \right.$$

$$\frac{d\Gamma_\perp}{dq^2} = N_{K_{\perp}} |q|^2 V_{-}(q^2)^2 \left( |C_9' + |C_{10}'|^2 + \left| C_9' + \frac{2m_b m_B}{q^2} C_7 T_{-}(q^2) - 8\pi^2 h_{K_{\perp}} |^2 \right) + O\left( \frac{\Lambda}{m_B} \right), \right. \right.$$

In this formula $N_{K^0,\perp}$ are dimensionful constants, $V_0(q^2)$ and $T_{-}(q^2)$ are form factors in the helicity basis [25], and $h_{K^0,\perp}$ describe the contributions from the four-quark and chromomagnetic operators much like $h_K$ above. Furthermore, we have neglected the hadronic matrix elements giving the leading contributions in the SM to decays into positively polarized $K^+$ [e.g. the form factors $V_+(q^2)$ and $T_{+}(q^2)$] because, in the large-recoil region (low $q^2$), they are suppressed by $O(\Lambda/m_b)$ [25]. In the SM these corrections, as well as, in general, the hadronic uncertainties, largely cancel in the $R_K$ ratios, formally appearing as $O(m_B^2/q^2 \times \Lambda/m_B)$ terms that will be systematically included in our numerical analysis.

The longitudinal contribution to the rate, Eq. (10), is similar to the $B \rightarrow K \ell^+ \ell^-$ one except that the chirally flipped operators interfere with the SM with a relative minus sign due to the different transformations under parity of the $B \rightarrow K$ and $B \rightarrow K^+$ hadronic matrix elements. In the transversal polarization, the interference of the chirally flipped operators with the SM is suppressed by the neglected $\Lambda/m_B$ terms in Eq. (11), so that their contributions will always increase $\Gamma_\perp$. Any scenario explaining the

FIG. 1. $R_K$ and $R_{K^*}$ (in the [1.1, 1.6] GeV$^2$ bin) parametric dependence on one Wilson coefficient at a time, for NP affecting only the muonic coefficients, where the nodes indicate steps of $\Delta(\delta C_{9}^{(\nu)}) = 0.5$ from the SM point and in the direction of the arrows. The red solid line shows the dependence on $\delta C_9^{(\nu)}$, dashed blue line on $\delta C_{10}^{(\nu)}$, green dot-dashed on $\delta C_{10}^{(\nu)}$, and orange dotted on $\delta C_{10}^{(\nu)}$.  

093006-3
The nodes indicate steps of the destructive interference that occurs in the SM and in various benchmark NP scenarios of lepton-universality ratios, along with our predictions in Table I, and are negligible as advertised. This is not longer true in presence of lepton-specific NP contributions, especially for the case of the \( R_{K^{0}} \).\(^{3}\) It is important to stress that radiative electromagnetic corrections, which break lepton universality and can reach the \(<2\%\) level at the level of the measured ratios \(^{2}\), have not been included in our predictions.

The dependence on the Wilson coefficients of interest of \( R_{K^{0}} \) and \( R_{K^{-}} \) in the bins \([1, 6]\) GeV\(^2\) and \([1.1, 6]\) GeV\(^2\), respectively, as functions of the Wilson coefficients of the four semileptonic operators can be expressed as

\[^{2}\) In this paper we will not consider new physics in \( C_{i}^{(0)} \) that could contribute through these interference terms. These Wilson coefficients are very tightly constrained by the decay \( B \rightarrow X_{s} \gamma \), the time dependent \( CP \)-asymmetry of \( B \rightarrow K^{*} \gamma \) and the angular analysis of \( B \rightarrow K^{*} e e \) a very low \( q^2 \)\(^{29, 48, 49}\).

\[^{3}\) It is interesting to note, though, that effects in \( R_{K^{0}} \) of lepton-specific contributions to \( \delta C_{i}^{0} \) should be enhanced around the mass of resonances (charmoniums at high-\( q^2 \)) or the \( \phi \) at low-\( q^2 \) because of the interference effects.
where the numerical coefficients have been obtained using Ref. [29] at a scale $\mu = 4.65$ GeV. These formulas give results on the ratios which are accurate at the $\sim 1\%$ level (which is better than the hadronic uncertainties) when compared to the exact numerical calculation and can be directly used to obtain predictions for NP effects in muons or in electrons.

In light of the discussion above and given the deficits observed in both $R_K$ and $R_{K^*}$ we conclude that the primed operators $O_{9,10}'$ are disfavored by the data. Henceforth we will focus only on the analysis of the operators $O_9$ and $O_{10}$.

**IV. FITS TO $R_K$ AND OTHER $b \to s\ell\ell$ DATA**

In this section we assess the compatibility with the SM of lepton-universality-violating and -conserving rare $B$-decay measurements, and perform frequentist fits to (NP values of) Wilson coefficients in the weak Hamiltonian. In all cases, theoretical uncertainties are modeled by adding a “theory term” to the $\chi^2$,

$$\chi^2(C,\bar{y}) = \chi^2_{\text{exp}}(C,\bar{y}) + \chi^2_{\text{th}}(\bar{y}).$$

Here $\chi^2_{\text{exp}}(C,\bar{y})$ is constructed in the usual way out of the experimental measurements considered, and the theoretical expressions for them in terms of a vector of Wilson coefficients $C$ included in a given fit, and the 27-component vector $\bar{y}$ of hadronic parameters that enter in the model-independent description of the $B \to K^*\ell\ell$ [25,29]. The theory term is taken in Gaussian form

$$\chi^2_{\text{th}}(\bar{y}) = \sum_i \left( \frac{y_i - \bar{y}_i}{\delta y_i} \right)^2,$$

where $\bar{y}_i$ are the central values of the theory parameters and $\delta y_i$ their estimated uncertainties, which we assume to be fully uncorrelated [29].

Once it is in this form, we treat the $y_i$ as nuisance parameters and construct a profile $\chi^2$ that depends on the Wilson coefficients only,

$$\chi^2(C) = \min_{\bar{y}} \chi^2(C,\bar{y}),$$

from which we determine frequentist confidence level intervals and contours for the Wilson coefficients. The construction here is nothing but the Rfit method [51] with Gaussian theory errors instead of parameter ranges.

**A. Fits only to $R_K$ and $R_{K^*}$**

We begin by considering $R_K$ and $R_{K^*}$ alone. Setting the Wilson coefficients to their SM values, we obtain $\chi^2_{\text{min.SM}} = 19.51$ with 3 degrees of freedom (d.o.f.), corresponding to a $p$-value of $2.1 \times 10^{-4}$ or a $3.7\sigma$ deviation. It must be stressed that the significance of this evidence for new physics in lepton-universality ratios alone is fully dominated by experimental statistical errors, with hadronic uncertainties (the $y_i$-parameters) playing almost no role, due to the exceptional cleanliness of the observables. Nonetheless, in our fit we include the theoretical errors of $R_{K^*}$ at low $q^2$ and investigate below the robustness of our fits against variations of the theoretical error ranges.

---

4Theoretical uncertainties for $R_K$ are always very small compared to the experimental errors in all scenarios considered (see Fig. 2 and Table I) and are neglected in our analysis.
We next show that a good fit is obtained by allowing for lepton-specific contributions $\delta C^l_9$ and $\delta C^l_{10}$. In Table II and Fig. 3 we display the results of one- and two-dimensional fits of muon-specific NP Wilson coefficient values $\delta C^\mu_9$ and $\delta C^\mu_{10}$.

Good to excellent fits are obtained in one-parameter scenarios where only $\delta C^\mu_{10}$, $\delta C^\mu_L = -\delta C^\mu_{10}$, or $\delta C^\mu_9$ are nonzero, as well as in the two-parameter scenario. The largest $p$-value (best fit) is obtained in the pure $C^\mu_{10}$-case, though the differences are not large. We next consider $\Delta\chi^2 = \chi^2 - \chi^2_{\text{min}}$ and use it to compute the significance at which the SM point (origin) is excluded (often called “pull”) and to construct frequentist confidence regions. In each of the four scenarios, the SM point (origin) is excluded at 4$\sigma$ confidence, or close to it [see Table II, where we also display best-fit values and confidence intervals for the parameters (in the two-dimensional case, these are obtained by minimizing $\Delta\chi^2$ over the other parameter)].

Instead of considering muon-specific effects, we could have assumed an electron-specific effect, or a combination. In the former case, essentially the signs of the fitted Wilson coefficients are reversed, if only the LUV observables are considered.

**B. Fits to $R_K$, $R_{K^*}$ and $B_s \to \mu\mu$**

We now add $\overline{\text{BR}}(B_s \to \mu\mu)$ to the data set. It is theoretically very clean with NNLO QCD and NLO electroweak corrections known [53], and the sole hadronic parameter, the decay constant $f_{B_s}$, having been precisely computed by different lattice QCD Collaborations [54]. To simplify the fit, we consider the ratio

$$R = \frac{\overline{\text{BR}}(B_s \to \mu\mu)}{\overline{\text{BR}}(B_s \to \mu\mu)_{\text{SM}}} = \left| \frac{C^\mu_{10}}{C^S_{10}} \right|^2,$$

where we have neglected the contributions of scalar operators. Among the set $(C^\mu_9, C^\mu_{10})$, this branching fraction only depends on the coefficient $C^\mu_{10}$, such that it is natural to add it to the fit of muon-specific Wilson coefficients. As experimental value for $R$ we employ the combination obtained in Ref. [55], $R_{\text{exp}} = 0.83(16)$, where the results from CMS and LHCb including run I and run II data have

---

5The overline refers to the fact that the experiments access the time-integrated branching ratio, which depends on the details of $B_s \bar{B}_s$ mixing [52].
TABLE II. Best fit values, goodness of fit, $p$-value, SM exclusion level (pull), and confidence intervals for fits of single or pairs of Wilson coefficients, to $R_K$ and $R_{K^*}$ data. For the one-dimensional case, we show the 1σ and 3σ confidence intervals, while for the two-dimensional case we show the 1σ intervals for the two parameters instead.

Again, all four scenarios considered provide good fits. The main impact on the two-parameter fit is that the allowed region is narrowed down considerably, with large positive correlated values of $\delta C_3^u$ and $\delta C_9^u$ no longer allowed. We note, in particular, that the combination of $C_L^u = \frac{1}{2}(C_3^u + C_9^u)$ is nonzero at more than 4σ significance and is relatively well determined by the LUV data set plus $B_s \rightarrow \mu\mu$ alone, irrespective of and in contradistinction from the value of $C_L^u = \frac{1}{2}(C_3^u + C_9^u)$, which is consistent with zero and poorly constrained.

C. Fits to $R_K$, $R_{K^*}$, $B_s \rightarrow \mu\mu$ and $B \rightarrow K^*\ell\ell$ data

We now include in the fits all measurements of the angular distribution in $B \rightarrow K^*\mu\mu$ by LHCb, ATLAS, CMS, and Belle in the low-$q^2$ region $q^2 \lesssim 6$ GeV$^2$ (except for lepton-universality differences measured by Belle, for which we do include the [4, 8] GeV$^2$ bin). The reason for this restriction is that we can then reasonably estimate the size of the hadronic uncertainties. As advertised above, we will later quantify the robustness of our conclusions with respect to the size of the theoretical errors. The precise data set comprises

(i) LHCb: The 32 measurements of the CP-averaged angular observables $F_L$, $P_1$, $P_2$, $P_3$, $P_4$, $P'_5$, $P_6'$, $P_8'$ in the bins [0, 0.1, 0.08] GeV$^2$, [1, 1.2, 5] GeV$^2$, [2.5, 4] GeV$^2$ and [4, 6] GeV$^2$ [9] including, inside of each bin, the published correlations among the observables.

(ii) ATLAS: The 18 measurements of the CP-averaged angular observables $F_L$, $P_1$, $P_4$, $P_5$, $P_6'$, $P_8'$ in the bins [0.04, 2] GeV$^2$, [2.4] GeV$^2$, [4, 6] GeV$^2$ reported in

![FIG. 4. Contours at 1σ and 3σ level in the ($\delta C_3^u, \delta C_9^u$) plane, in solid lines and orange and light-red colors, for the fit to $R_K$, $R_{K^*}$ and $\mathcal{BR}(B_s \rightarrow \mu\mu)$. We also show the 1σ and 3σ constraints given individually by $R_K$, $R_{K^*}$ in the [1, 1.6] GeV$^2$ bin and $\mathcal{BR}(B_s \rightarrow \mu\mu)$ using blue, green and gray contours, respectively. The cross indicates the position of the minimum.](image-url)
Correlations of this data are not public and are neglected.

(iii) CMS: The six measurements of the CP-averaged angular observables $P_1$ and $P_3'$ in the bins $[1, 2]$ GeV$^2$, $[2, 4.3]$ GeV$^2$, $[4.3, 6]$ GeV$^2$ reported in Moriond EW 2017 [12]. Correlations of this data are not public and are neglected.

(iv) Belle: The four measurements of the CP-averaged lepton universality differences of angular observables $Q_4$ and $Q_5$ in the bins $[1, 4]$ GeV$^2$ and $[4, 8]$ GeV$^2$ [10]. Correlations of this data are not public and are neglected.

In addition, we include in the fit the BR($B \to K^*\gamma$) [56–60] which provides an important constraint to a hadronic form factor in the fit [29]. Including the measurements of $R_K$, $R_{K^*}$ and BR($B_s \to \mu \mu$), the total number of measurements in the fit is 65.

The resulting $\chi^2_{\text{min}}$ SM-value is 81.1 [65 d.o.f.], corresponding to a $p$-value of 0.086. Note that this is considerably larger than before—adding the many angular observables, the significance of the anomalies has decreased. Each of the four models we consider provides an excellent fit, once the full data set is considered. At the same time, the significance of the SM exclusion in three of the four fits is above 4$\sigma$; we show fit results in Table IV. The main impact on the fits is to narrow down the $C_9^u$ range further, excluding positive values at high confidence. Note that the axes of the, approximately elliptic, allowed region in the two-parameter fit are nearly aligned with the $C_9^u$ and $C_{R}$ directions, in such a fashion that $C_9^u$ is again nonzero at more than $4\sigma$ confidence, while $C_{R}$ is more or less consistent with zero and much less well determined.

Finally, we consider the measurements of $B \to K^*e^+e^-$ performed by LHCb, namely of the branching fraction [61], as well as of four angular observables [48] with a reduced form-factor dependence similarly to the muonic case. A fit including the resulting 70 measurements is shown in Fig. 5. Including or omitting the electron data has only a minimal impact on the fit and statistical tests.

### D. Robustness of fit with respect to hadronic uncertainties

We investigate the robustness of our fits to the theoretical uncertainties of the $B \to K^*\mu \mu$ amplitude, which can affect considerably the predictions of the angular analysis and, therefore, the tensions of the SM with the data. In order to do so, we perform a scan of the variable $x$, that is a factor by which we multiply all the uncertainty ranges of the theoretical parameters in Eq. (14), in the range $x \in [0.5, 3]$. At each $x$, we calculate the variation of the $\chi^2_{\text{d.o.f.}}$ with respect to $x$ in the SM in the fit to only $R_K$, $R_{K^*}$ and BR($B_s \to \mu \mu$). The results are shown in Fig. 6 by the blue solid curve, which demonstrates the stability, with respect to the hadronic uncertainties in the semileptonic decays, of the fits to the lepton-universality ratios. This is just a consequence of the cancellations of hadronic uncertainties in the ratios discussed in previous sections. For illustrative purposes, we compare with the fit in which we

also include the 61 measurements of observables in the angular distribution of $B \to K^\ast \mu\mu$ and the radiative $B \to K\gamma$ decay, which shows a much stronger sensitivity, as expected. A more careful treatment of hadronic uncertainties and their impact in the interpretation and analysis of the robustness of the global fits is left for future studies.

### E. Beyond muon-specific lepton nonuniversality

As already noted, our choice to focus on new physics in muonic Wilson coefficients $C_9^\mu$, $C_{10}^\mu$ was far from mandatory. As an example of a more general scenario that can accommodate the data, in the left panel of Fig. 7, we show two-parameter fits of $C_L^\mu$ and $C_L^\nu$, to LUV data and $B_s \to \mu^+\mu^-$ and the full data set. In both cases, a high degree of degeneracy is seen, and pure $C_L^\mu$ fits the data nearly as well as $C_L^\nu$.

In the right panel of Fig. 7 we consider instead a two-parameter scenario with a muon-specific Wilson coefficient $C_L^\mu$ and a lepton-flavor-universal coefficient $C_9^\mu = C_5^\mu = C_9$. Such a universal coefficient is generically expected to be generated in BSM scenarios at the one-loop level through penguin diagrams. One particular realization is the “charming BSM scenario” of [62]. In fact, this “semiuniversal” scenario fits the data minimally better the pure-$C_L^\mu$ ($p = 62\%$ versus $p = 60\%$). This preference for an extra $C_9$ effect can be understood as a consequence of the $B \to K^\ast \mu^+\mu^-$ angular distribution measurements (particularly the $P_\gamma$ term); because the $B \to K^\ast e^+e^-$ measurements are much less precise and only cover $q^2 < 1.12$ GeV$^2$, the data do not require this to be muon-specific. The preference for an extra, possibly universal, $C_9^\text{univ}$ effect would increase with more optimistic error estimates on $B$-decay form factors that are sometimes made in the literature.

### V. Precision Probes of a Lepton-Nonuniversal $C_{10}$

As shown above, low values of $R_K$ at small dilepton mass, as suggested by the new LHCb measurements, require a modification of $C_{10}^\mu$. However, the value of $C_{10}^\mu$ is poorly determined by the global fit: while the combination $C_L^{\mu} = (C_{10}^\mu - C_{10})/2$ is already well determined and significantly different from zero, the combination $C_L^\nu = (C_9^\mu + C_{10}^\mu)/2$ is poorly constrained. Breaking the degeneracy between $C_9^\mu$ and $C_{10}^\mu$ will be a key requirement for identifying the dynamics underlying the NP signals. Currently, the most precise selective probe of the coefficient $C_{10}^\mu$ is the $B_s \to \mu^+\mu^-$ branching fraction, but this suffers from low statistics. In this section we describe observables which are selectively sensitive to a lepton-nonuniversal $C_{10}$ effect at a (theoretical) precision better...
than the percent level. They are sensitive to $C_{10}$ as well as $C_{10}''$.

The starting point is the observation that the angular distribution in $B \to K^* \ell^+ \ell^-$ contains a single term proportional to $C_{10}$, commonly called $I_6$, due to vector-axial-vector interference and responsible for the lepton forward-backward asymmetry. In terms of the helicity amplitudes,

$$I_6^{(\ell)} = NC_{10} q^2 \beta_\ell^2(q^2) |\vec{k}|$$

$$\times \left( \text{Re}[H_{V-}^{(\ell)}(q^2)] V_-(q^2) + \text{Re}[H_{V+}^{(\ell)}(q^2) C_{10}''(q^2)] \right),$$

where $N$ is a $q^2$-independent normalization, and $\beta_\ell^2 = 1 - 4m_\ell^2/q^2$ is the velocity-squared of the lepton in the dilepton rest frame (equal to one for electrons, for practical purposes). As shown in [25,29], the amplitude $H_{V+}$ is suppressed relative to $H_{V-}$ by $q^2 \Lambda/m_B^3$ at small $q^2$-values. Moreover, if the disfavored Wilson coefficients $C_{10}''$ and $C_{10}''$ are neglected, $H_{V+}^{(\ell)} = C_{10}'' V_+$ is itself suppressed by one power of $\Lambda/m_B$ in the heavy-quark limit. The second term hence gives at most a 1% contribution below $q^2 = 1$ GeV$^2$ (but will be kept in our numerics).

Following [29], we define

$$R_6[a,b] = \frac{\int_a^b \Sigma_6 dq^2}{\int_a^b \Sigma_6 dq^2} C_{10}'' \times \left( \frac{\int_a^b |\vec{k}|q^2 \beta_\ell^2 \text{Re}[H_{V-}^{(\ell)}(q^2)] V_-(q^2)}{\int_a^b |\vec{k}|q^2 \text{Re}[H_{V+}^{(\ell)}(q^2)] V_-(q^2)} \right),$$

where $\Sigma_6$ is the $CP$-average of $I_6$. The sensitivity of $R_6$ to deviations from $C_{10}''/C_{10}''$ from one is evident from the direct proportionality exhibited in (18). It was noted in [29] but not quantified. Moreover, the constant of proportionality—the ratio of integrals—differs from one only through the exactly known velocity-factor $\beta_\ell^2$ and possible lepton-flavor-universality violation in $H_{V-}$. The only source of such lepton-flavor-nonuniversality would be a lepton-nonuniversal $C'_{q}$, due to the dominance of the photon pole at small $q^2$, for $|C_{q}^{NP}| \lesssim 1$ the resulting modification of $H_{V-}$ is at the 5% level at $q^2 = 1$ GeV$^2$ and drops roughly linearly with $q^2$ below. Since $\Sigma_6$ is rather flat in $q^2$ below 1 GeV$^2$ (see Fig. 6 in [25]), we conclude that the impact of NP effects in $C_{q}^{NP}$ in $R_6[0.045, 1.1]$ is at most 2%–3%. Moreover, this small effect is calculable with $O(10\%–20\%)$ relative accuracy in the heavy-quark expansion. As a result, if $\delta C_{10} = 0$ then $R_6$ can theoretically determine $\delta C_{10}''$ to an (absolute) accuracy of about 0.13 irrespective of the value of $\delta C_{q}''$. Below that level, $R_6$ still probes a combination of (mainly) $\delta C_{10}''$ and $\delta C_{10}''$, which may still be useful in disentangling the two in the context of a global fit.

Figure 8 shows $R_6$ for the bin $[0.045, 1.1]$ GeV$^2$ as a function of $C_{10}''$ for three scenarios differing in $\delta C_{q}$. The sensitivity to $\delta C_{10}''$ is evident from the slope and the narrowness of the bands in the figure, while the near-degeneracy of the three bands illustrates the insensitivity to $\delta C_{q}''$. Numerical values are given in Table V. They corroborate the preceding discussion and show that $R_6$ can clearly discriminate between the two benchmarks that remain viable in light of the $R_K$ measurements.

From an experimental perspective, $R_6$ may benefit from cancellations of certain systematics in the ratio, and from the fact that both numerator and denominator are rather flat in $q^2$, which reduces the impact of energy-resolution uncertainties. Alternatively, one may consider the following two observables, closely related to $R_6$:

$$\bar{R}_6 = \frac{\langle A_{FB}^2 \rangle}{\langle A_{FB}^2 \rangle} = R_6/R_{K^+}, \quad R'_6 = \frac{\langle P_{2}^{(\ell)} \rangle}{\langle P_{2}^{(\ell)} \rangle},$$

where $A_{FB}$ is the forward-backward asymmetry and $P_{2}$ is the corresponding “optimized observable” defined in

Ref. [63], and where we have omitted the limits $[a, b]$ in the binning $\langle \ldots \rangle$ of the observables. For example, $\bar{R}_6$ has numerator and denominator normalized to the respective integrated decay rate, such that a double ratio with $\Gamma(J/\psi \mu \mu)/\Gamma(J/\psi ee)$ may be considered, similarly to the $R_K$ and $R_{K^*}$ measurements. $R_6$, $\bar{R}_6$, and $R'_6$ are theoretically equally clean and have the same $C''_{10}/C''_{10}$ analyzing power as $R_6$. The extreme insensitivity of $R'_6$ to the values of $C''_9$ displayed in Table V and in Fig. 8 is remarkable and turns these observables into the optimal analyzer of lepton nonuniversality in $C''_{10}$. However, the relatively larger sensitivity to $C''_9$ in $\bar{R}_6$ relative to $R'_6$ is strongly correlated with that in $R_{K^*}$, such that a joint measurement of $R_{K^*}$ and $\bar{R}_6$ can still determine $C''_{10}$ precisely. By contrast, the observable $Q_2$ defined in [42] is sensitive to form factor ratios. It is a clean null test of lepton flavor universality, but does not provide a similarly precise determination of its violation, cf. Table V.

In consequence, the choice among $R_6$, $\bar{R}_6$, and $R'_6$ should be guided by what minimizes experimental systematics. Most excitingly, a useful determination of each of these should be possible with existing data, both at LHCb and Belle. We illustrate this in Fig. 9 with the impact in the ($C'_6$, $C''_{10}$)-plane of a hypothetical measurement of $R'_6 = 0.80(5)$ in the bin $[0.045, 1.1]$ GeV$^2$, shown together with the result of the fit to $R_6$ and $R_{K^*}$ and the combined result. We end by noting that we have not considered in our discussion of these new observables the effect of the electromagnetic radiative corrections, which can be more severe for the ultralow bin. However, as discussed in [2] these can be minimized by choosing a more suitable bin starting at 0.1 GeV$^2$, for which all the conclusions above will still apply.

VI. CONCLUSIONS

In this paper we have analyzed the deficits, with respect to the Standard-Model expectations, of the lepton-universality ratios $R_{K^*}$ recently measured by the LHCb. We first described the structure of the new-physics contributions to the $B \to K \ell^+ \ell^-$ and $B \to K^* \ell^+ \ell^-$ rates and the resulting correlations induced between $R_K$ and $R_{K^*}$. We then presented the predictions of $R_{K^*}$ in the bins of interest for the SM and in benchmark scenarios of new physics using a model-independent approach for the description of the $B \to K^* \ell^+ \ell^-$ amplitude. The cleanness of these observables, with respect to hadronic uncertainties, is discussed and demonstrated numerically. Furthermore, we provide numerical formulas for the dependence of $R_{K^*}$ as functions of the Wilson coefficients which can be useful for phenomenological applications. Finally, we discarded the primed operators $O''_{9(10)}$ as they induce a correlation between $R_K$ and $R_{K^*}$ that is opposite to the observed one.

Next, we perform fits to different sets of data within a frequentist approach in which the hadronic uncertainties are systematically included and minimized in the fits. We begin with the analysis of $R_{K^{(*)}}$ only, finding that the best fit is provided by combinations of the $O''_{9(10)} = \bar{\psi}\gamma\mu_b \bar{\ell} \gamma_{\mu}(\gamma_5) \ell$ operators with a significance with respect to the Standard Model of $\sim 4\sigma$. An important conclusion of this analysis is that a lepton-specific contribution to $O''_{9(10)}$ is essential to understand the data. Under the hypothesis that
new-physics couples selectively to the muons, we then present a series of fits to other $b \to s \mu \mu$ data with a conservative error assessment. First we include only the branching fraction of the $B_s \to \mu \mu$ decay, which provides a significant constraint that drifts the best fit point to a “chiral” left-handed solution $\mathcal{O}_6 - \mathcal{O}_{10}^r$, but does not significantly increase the tension of the data with the SM.

In the last fit we include all the angular observables measured by LHCb, ATLAS, CMS and Belle for the bins below 6 GeV$^2$. As previous fits in the literature, measurements of the angular observables tend to pull the Wilson coefficient $\delta C_9^\mu$ to negative values with a significance of more than $3\sigma$, while rendering $\delta C_{10}^\mu$ consistent with 0 at $\sim 1\sigma$. The results of these fits, rephrased in terms of $C_9^\mu / C_{10}^\mu = (C_9^\mu + C_{10}^\mu) / 2$, show that $C_9^\mu$ is very well determined by the fit $\delta C_9^\mu = -1$ while $C_{10}^\mu$ is not. We have also noted, however, the potential vulnerability of the results of this fit to underlying assumptions regarding the hadronic uncertainties, as it has been discussed extensively in the literature. In order to quantify this, we have made a study of the robustness of the tensions of the SM with the data for different assumptions regarding the size of the hadronic uncertainties. We emphasize again that this problem is absent in the fits to only $L=R$ uncertainties. We introduce and discuss a group of robustness of the tensions of the SM with the data for different assumptions regarding the size of the hadronic uncertainties, as it has been discussed extensively in the literature. In order to quantify this, we have made a study of the robustness of the tensions of the SM with the data for different assumptions regarding the size of the hadronic uncertainties. We emphasize again that this problem is absent in the fits to only $L=R$ uncertainties. We introduce and discuss a group of

Therefore, we introduce and discuss a group of lepton-universality ratios all related to the coefficient of the angular distribution $I_6$ (or the forward-backward asymmetry) which are very sensitive to lepton nonuniversality in the Wilson coefficient $C_9^\mu$ and are largely insensitive to new-physics contributions to $C_9$ in the low-$q^2$ bin. A measurement of these observables would break the correlation between the lepton-specific effects in $\mathcal{O}_6$ and $\mathcal{O}_{10}^r$ observed in the fits to $R_K$ and $\Delta R_K$. In light of the fact that the two observables $P_\mu$ have been measured by the LHCb for electrons and muons respectively at very low $q^2$ (though using a different binning), one is tempted to think that a measurement of the ratios proposed in this paper is feasible in the near future. We present prospects of the impact of such a measurement in the $(C_9^\mu, C_{10}^\mu)$ plane, which could help clarifying the nature of the observed effects and contribute to the discovery of the new physics in $b \to s l^+ l^-$ transitions.
