Abstract

IMPORTANCE: Burnout is prevalent in physicians and can have a negative influence on performance, career continuation and patient care. Existing evidence does not allow clear recommendations for the management of burnout in physicians.

OBJECTIVE: To evaluate the effectiveness of interventions to reduce burnout in physicians. We also examined whether different types of interventions (physician-directed or organization-directed interventions), physician characteristics (length of experience) and healthcare setting characteristics (primary or secondary care) were associated with improved effects.

DATA SOURCES: Medline, Embase, PsycINFO, Cinahl, and Central, were searched from inception to May 2016. The reference lists of eligible studies and other relevant systematic reviews were hand-searched.

STUDY SELECTION: Randomized controlled trials and controlled before-after studies of interventions targeting burnout in physicians.

DATA EXTRACTION AND SYNTHESIS: Two independent reviewers extracted data and assessed the risk of bias. The main meta-analysis was followed by a number of pre-specified subgroup and sensitivity analyses. All analyses were performed using random-effects models and heterogeneity was quantified using $I^2$.

MAIN OUTCOME AND MEASURES: The core outcome was burnout scores focused on emotional exhaustion, reported as standardized mean differences and their 95% confidence intervals.

RESULTS: Twenty independent comparisons from 19 studies were included in the meta-analysis (n=1,550 physicians). Interventions were associated with small significant reductions in burnout (SMD=-0.29, 95% CI=-0.42 to -0.16; equal to a drop of 3-points on the emotional exhaustion domain of the Maslach Burnout Inventory above change in the controls). Subgroup analyses suggested significantly improved effects for organization-
directed interventions (SMD=-0.45, 95% CI=-0.62 to -0.28) compared to physician-directed interventions (SMD=-0.18, 95% CI=-0.32 to -0.03). Interventions delivered in experienced physicians and in primary care were associated with higher effects compared to interventions delivered in inexperienced physicians and in secondary care, but these differences were not significant. The results were not influenced by the risk of bias ratings.

CONCLUSION: Evidence from this meta-analysis suggests that current intervention programs for burnout in physicians are associated with small benefits which may be boosted by adoption of organization-directed approaches. This finding provides support for the view that burnout is a problem of the whole healthcare organization, rather than individuals.
Introduction

Burnout is a syndrome consisting of emotional exhaustion, depersonalization, and a diminished sense of personal accomplishment, which is primarily driven by workplace stressors.\(^1\)-\(^3\) Burnout is a major concern for physicians. Nearly half of practicing physicians in the United States experience burnout at some point in their career \(^4\).

Although there are substantial differences by specialty, physicians at the front line of care report the highest rates of burnout.\(^5\)

Burnout has serious negative consequences for physicians, the healthcare system and for patient outcomes. Burnout in physicians has been linked with lower work satisfaction, disrupted personal relationships, substance misuse, depression, and suicide.\(^6\),\(^7\) Within health care organizations, burnout is related to reduced productivity, high job turnover and early retirement.\(^8\),\(^9\),\(^10\) Importantly, burnout can result in an increase in medical errors, reduced quality of patient care and lower patient satisfaction.\(^11\)-\(^16\) It is not surprising therefore, that wellness of physicians is increasingly proposed as a quality indicator in healthcare delivery.\(^17\)

Leading drivers of burnout include excessive workload, imbalance between job demands and skills, a lack of job control, and prolonged work stress.\(^18\) Recently, there has been a shift from viewing burnout as an individual problem, to a problem of the healthcare organization as a whole; rooted in issues related to working environment and organizational culture.\(^19\) It has been suggested that reducing risk of burnout in physicians requires change in organizations, as well as support for individual physicians.\(^20\)
Interventions for burnout can be classified into two main categories, physician-directed interventions targeting individuals and organization-directed interventions targeting the working environment.\textsuperscript{21-23} Physician-directed interventions typically involve mindfulness techniques or cognitive behavioral techniques to enhance job competence, improve communication skills and personal coping strategies. Organization-directed interventions can involve simple changes in schedule and reductions in the intensity of workload or more ambitious changes to the operation of practices and whole healthcare organizations. These usually involve improved team-working, changes in work evaluation, supervision to reduce job demand and enhance job control, and increasing the level of participation in decision making.

One recent systematic review and meta-analysis of interventions to reduce burnout in physicians was identified. This study showed that interventions were associated with medium to small significant reductions in all three components of burnout. However, the types of interventions and the research designs analyzed were heterogeneous. Uncertainties remain whether contextual factors such as differences in the healthcare settings and physician characteristics moderate these findings. Prior to this publication, a Cochrane review of interventions for work stress in healthcare professionals\textsuperscript{22} and another review which focused on aspects of well-being in primary care physicians had been published.\textsuperscript{24} The Cochrane review synthesized interventions of work stress in healthcare professionals, but the majority of studies were derived from interventions in nurses, not physicians.\textsuperscript{25} The other systematic review was very limited in focus; only 4 interventions aiming to improve an overall sense of well-being in general practitioners were included in the review.\textsuperscript{24}

156  Interventions for burnout can be classified into two main categories, physician-
157  directed interventions targeting individuals and organization-directed interventions
158  targeting the working environment.\textsuperscript{21-23} Physician-directed interventions typically
159  involve mindfulness techniques or cognitive behavioral techniques to enhance job
160  competence, improve communication skills and personal coping strategies.
161  Organization-directed interventions can involve simple changes in schedule and
162  reductions in the intensity of workload or more ambitious changes to the operation
163  of practices and whole healthcare organizations. These usually involve improved
164  team-working, changes in work evaluation, supervision to reduce job demand and
165  enhance job control, and increasing the level of participation in decision making.
166
167  One recent systematic review and meta-analysis of interventions to reduce burnout
168  in physicians was identified. This study showed that interventions were associated
169  with medium to small significant reductions in all three components of burnout.
170  However, the types of interventions and the research designs analyzed were
171  heterogeneous. Uncertainties remain whether contextual factors such as differences
172  in the healthcare settings and physician characteristics moderate these findings. Prior
173  to this publication, a Cochrane review of interventions for work stress in healthcare
174  professionals\textsuperscript{22} and another review which focused on aspects of well-being in
175  primary care physicians had been published.\textsuperscript{24} The Cochrane review synthesized
176  interventions of work stress in healthcare professionals, but the majority of studies
177  were derived from interventions in nurses, not physicians.\textsuperscript{25} The other systematic
178  review was very limited in focus; only 4 interventions aiming to improve an overall
179  sense of well-being in general practitioners were included in the review.\textsuperscript{24}
We conducted a systematic review and meta-analysis of studies which evaluated interventions to reduce burnout in physicians. We decided to focus on burnout scores as the main outcome of this review because burnout is the best recognized serious negative consequence of work stress in physicians and the most commonly reported, and consistently measured, outcome of work stress interventions. Moreover, by focusing on burnout, we established a level of homogeneity in terms of outcomes which allowed us to test our aims meta-analytically. Our first objective was to assess the effectiveness of interventions in reducing burnout. Second, we examined what types of interventions are the most effective (organization-directed, physician-directed). Thirdly, we examined whether there are any differences in the effect of interventions in different healthcare settings (primary care, secondary/intensive care) and in physicians with different levels of working experience. Our rationale was that physicians working in different organizational settings or physicians with different levels of experience might have diverse needs and might respond differently to burnout interventions.

Methods

The reporting of the review adheres to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement (eTable 1). The protocol is included in eMethods1.

Eligibility criteria

- Population: Physicians of any specialty in primary, secondary or intensive care setting including residents and fellows. Studies based on a mix of physicians and other healthcare professionals were included in the review if the physicians comprised 70% of the sample.
Intervention: Any intervention designed to improve stress/performance of physicians and reported burnout outcomes including physician-directed interventions and organization-directed interventions. Physician-directed interventions focused on individuals (e.g. cognitive behavioral therapies, mindfulness stress reduction techniques, educational programs for improving communication skills) whereas organization-directed interventions introduced changes in the resources, the working environment, work tasks to decrease stress (e.g. changes in the intensity/schedule of workload or deeper improvements in the operation of healthcare organizations and the teamwork).

- Comparison: Any type of control (e.g. waiting list or no intervention)

- Outcome: Burnout measured using validated tools such as the Maslach Burnout Inventory (MBI),\textsuperscript{1} or other validated measures that measured burnout.

- Study design: Quantitative intervention designs described in the Cochrane handbook including RCTs, non-randomized trials, controlled before-after studies and interrupted time-series.

- Context: Any healthcare setting including primary care and secondary care.

Exclusion criteria:

- Interventions not reporting data on burnout outcomes but providing data on general stress, well-being or job satisfaction.

- Grey literature

**Search strategy and data sources**

Five electronic bibliographic databases were searched from inception until May 2016: MEDLINE, EMBASE, CINAHL, Cochrane Register of Controlled Trials and PsycINFO. The
search strategy included combinations of three key blocks of terms (burnout; physicians; interventions) using medical subject headings (MESH terms) and text-words (eMethods2). Searches were supplemented by hand searches of the reference lists of eligible studies and systematic reviews.

**Study selection**

The results of the searches were exported in Endnote and duplicates were removed. Study selection was completed in two stages. First, the titles and abstracts of the studies were screened and subsequently the full-texts of relevant studies were accessed and further screened against the eligibility criteria. The title/abstract screening was undertaken by the first author whereas two independent reviewers were involved in full-text screening. Inter-rater reliability was high (kappa = 0.96). Disagreements were resolved through discussions.

**Data extraction**

An Excel data extraction form was developed and initially piloted in five randomly selected studies. Quantitative data for meta-analysis were extracted on a separate extraction sheet. Authors were contacted when data were missing or incomplete. The following descriptive information was extracted from the studies:

- **Study:** research design, method of recruitment and content of control
- **Participants:** sample size, age, gender, setting/specialty, years of work experience
- **Intervention:** content, delivery format, intensity, follow-up time points
- **Outcomes:** scores in burnout including emotional exhaustion, depersonalization and professional accomplishment.

**Risk of bias assessment**
The critical appraisal of the studies was performed using the Effective Practice and Organisation of Care (EPOC) risk of bias tool. EPOC was chosen because it is appropriate for use across all types of intervention designs described in the Cochrane handbook. The EPOC tool contains nine standardized criteria scored on a 3-point scale, corresponding to low, unclear, and high risk.

Data analysis

Standardized Mean Differences (SMDs) and associated confidence intervals (CI) for the burnout outcomes of all the studies were calculated in Comprehensive Meta-Analysis (CMA). The pooled SMDs and the forest plots were computed using the metan command in Stata 14. The main meta-analysis evaluated the effectiveness of the interventions in reducing burnout. The MBI measure for burnout provides ratings in three domains (emotional exhaustion, depersonalization and personal accomplishment). It is not recommended they are combined. In line with previous meta-analyses, we used only the emotional exhaustion domain of MBI in the analyses. Emotional exhaustion is considered the most central aspect of burnout (some studies only use this domain) and other unidimensional measures of burnout focus on emotional exhaustion. To ease the interpretation of the results we “back-transformed” the pooled SMD to a mean difference for the emotional exhaustion subscale, under certain assumptions. When data were available for more than one follow-up assessment points, the short-term assessment point were inserted in the main analysis. Three pre-specified subgroup analyses were carried out:

i. Type of interventions – we tested the effectiveness of physician-directed, and organization-directed interventions.
ii. Working experience of physicians – we examined the differential treatment effects across studies recruited physicians with extensive working experience (mean = 5 years or more) and studies recruited physicians with low experience (mean= less than 5 years). All studies classified into the low experience category explicitly reported in the methods that they recruited junior physicians.

iii. Healthcare setting – we tested the effects of interventions separately in physicians based in primary care and in secondary care.

Two sensitivity analyses were performed. We examined the effects of interventions on the other two domains of MBI (depersonalization and personal accomplishment). We also examined whether effects were robust when only studies with low risk of bias scores were retained in the analyses.

Heterogeneity was assessed using the $I^2$ statistic. Conventionally, $I^2$ values of 25%, 50%, and 75% indicate low, moderate, and high heterogeneity. All analyses were conducted using a random effects model, even if $I^2$ was low. Random-effects models are more conservative and have better properties in the presence of any heterogeneity. The Cohen’s Q test of between group variance was used to test whether the effectiveness of burnout interventions is significantly different across sub-groups. Cluster RCTs were identified and the precision of analyses adjusted using a sample size/variation inflation method, assuming an intra-class correlation of 0.02. Provided we identified 10 or more studies, we aimed to use funnel plots and Egger’s test to assess small sample bias (an indicator of possible publication bias). Funnel plots were constructed using the metafunnel command, and the Egger test was computed using the metabias command.
Results

The search strategy yielded 2,322 articles. Following the removal of duplicates, 1723 articles were retained for title and abstract screening. Of these, 75 were relevant for full-text screening and 19 studies were included in the review. One study included a marginally lower percentage of physicians (67%) but we retained it in the analyses to maximize the evidence base.

Characteristics of studies and physicians

Table 1 presents the characteristics of the 19 studies (including 20 independent comparisons on 1,550 physicians, mean age=40.3 years). Eight studies were conducted in the US (42%), four in Europe, three in Australia, two in Canada, one in Argentina and one in Israel. A higher proportion of men were recruited in the majority of studies.

Seven studies recruited physicians working in primary care (mostly labelled ‘general practitioners’), ten studies recruited physicians in secondary care (e.g. physicians in intensive care units, oncologists and surgeons) and two studies recruited a mixed sample of physicians who were recruited through their registration in national medical associations. Across all interventions, the main eligibility criteria were being a physician (working on a specific setting in most cases) and willingness to take part in the study. None of the studies specifically targeted physicians with certain severity levels of burnout. The majority of studies (n=12; 67%) were based on experienced physicians (mean working experience= 5 years and over) whereas seven studies were based on recently qualified physicians (mean working experience=less than 5 years). With the exception of one study, all used the MBI to assess the severity of burnout (eTable 2).
Characteristics of Interventions

Interventions varied considerably in their characteristics including content, duration/intensity, and length of post-intervention assessment points (see Table 1). The majority (n=12; 60%) were physician-directed interventions which comprised mindfulness stress reduction techniques, educational interventions targeting physicians’ self-confidence and communication skills, exercise or a combination of these features.

Within the category of organization-directed interventions, five studies evaluated simple workload interventions which focused on rescheduling hourly shifts and reducing workload. Only three studies tested more extensive organization-directed interventions incorporating discussion meetings to enhance teamwork and leadership, structural changes, and elements of physician interventions such as communication skills training and mindfulness.

The duration of the interventions ranged from 2 weeks to 9 months. Follow-up assessment points ranged from 1 day to 18 months post-intervention. All interventions were delivered in face to face format.

Risk of bias characteristics

The results of the risk of bias assessment are presented in eFigure 1. Eighteen comparisons were RCTs (95%) whereas two were CBA. Fifteen comparisons (75%) fulfilled 6 of the 9 risk of bias criteria (a higher score indicates lower vulnerability to bias). Three comparisons fulfilled 8 to 9 criteria (17%) while 5 fulfilled 4 or fewer criteria (25%); most moderately accounted for the risk of bias criteria.
Main meta-analysis: Effectiveness of interventions in reducing burnout

Interventions were associated with small, significant reductions in burnout (SMD=-0.29, 95% CI=-0.42 to -0.16, I² =30%, 95% CI=0 to 60; Figure 2). The back-transformed emotional exhaustion score for the intervention group was 15.1 (95% CI=13.9 to 16.5), compared to a control group score of 17.9 and assuming a standard deviation of 8.97 for the effect.

Subgroup analyses

Types of interventions: Physician-directed interventions were associated with small significant reductions in burnout (SMD=-0.18, 95% CI=-0.32 to -0.03, I²=11%, 95% CI=0 to 49; back-transformed emotional exhaustion score =16.2, 95% CI=14.7 to 17.3 compared to a control group score of 17.9) whereas organization-directed interventions were associated with medium significant reductions in burnout (SMD=-0.45, 95% CI=-0.62 to -0.28, I²=19%, 95% CI=0 to 60; back-transformed emotional exhaustion score=13.9, 95% CI=12.4 to 14.7 compared to a control group score of 17.9; Figure 3). The effects of organization-directed interventions were significantly larger than the effects of physician-directed interventions (Cohen’s Q = 4.15, P=0.04).

Working experience: The pooled effect of interventions on burnout scores was medium and significant across studies mainly based on experienced physicians (SMD=-0.37, 95% CI=-0.58 to -0.16, I²=42%, 95% CI=0 to 70; back-transformed emotional exhaustion score =14.6, 95% CI=12.7 to 16.5 compared to a control group score of 17.9) and small and significant across studies on physicians with limited experience (SMD=-0.27, 95% CI=-0.40 to -0.14, I²=0%, 95% CI=0 to 75; back-transformed emotional exhaustion score =15.5, 95% CI=13.8 to 16.9 compared to a control group score of 17.9; eFigure 2). This group difference was non-significant (Q=0.92, P=0.34).
Healthcare setting: Interventions in primary care were associated with small to medium reductions in burnout (SMD=-0.39, 95% CI=-0.59 to -0.19, $I^2=4\%$, 95%CI=0 to 69; back-transformed emotional exhaustion score =14.4, 95%CI=12.6 to 16.2 compared to a control group score of 17.9). Interventions in secondary care were associated with small significant reductions in burnout (SMD=-0.24, 95% CI=-0.41 to -0.07, $I^2=41\%$, 95%CI=0 to 65; back-transformed emotional exhaustion score = 15.7, 95%CI=13.9 to 17.4 compared to a control group score of 17.9; eFigure 3). This difference was non-significant ($Q=0.51$, $P=0.48$).

Sensitivity analyses

The treatment effect derived by studies at lower risk of bias (i.e. scoring low on 6 of the 9 risk of bias criteria) was similar to the overall effects of the main analysis (SMD=-0.32, 95% CI=-0.49 to -0.14, $I^2=42\%$, 95%CI=0 to 70; eFigure 4).

Interventions were associated with very small significant reductions in depersonalization (SMD=-0.21, 95% CI=-0.35 to -0.06, $I^2=33\%$, 95%CI=0 to 68%; eFigure 5) and small improvements in the personal accomplishment (SMD=0.30, 95% CI=0.15 to 0.45, $I^2=0\%$, 95%CI=0 to 58%; eFigure 6). The subgroup analyses in these two domains showed similar results but were based on a smaller number of studies (eTable 3).

Small study bias

We found no evidence of funnel plot asymmetry which might indicate publication bias for the main, or subgroup analyses (Egger test $P=0.11$ for main analysis; Figure 4).

Discussion

Summary of main findings
This meta-analysis showed that interventions for physicians are associated with small significant reductions in burnout. Organization-directed interventions were associated with higher treatment effects compared to physician-directed interventions. Interventions targeting experienced physicians and delivered in primary care showed evidence of greater effectiveness compared to interventions targeting less experienced physicians and delivered secondary care, but these group differences were non-significant.

Strengths and limitations

This is a comprehensive meta-analysis of controlled interventions aimed at reducing physician burnout. The two greatest threats for the validity of meta-analysis are heterogeneity and publication bias. However, the biggest strength of this work is the large number of identified and meta-analyzed controlled comparisons (20, when approximately 11.5% of all meta-analyses include 10 or more studies), which allows us to reliably estimate and model heterogeneity levels. In addition, the size of the meta-analysis allowed us to assess publication bias with adequate power. Although publication bias tests are rarely conclusive, we did not observe any bias indications in the plot or test.

The included studies differed significantly in terms of content of interventions, study design/quality and length of follow-up which limit the extent to which broad conclusions can be made about the overall effectiveness of physician interventions. However, estimates of heterogeneity in the pooled analyses were low to moderate by conventional thresholds and random effects models were applied in all analyses. Heterogeneity was further addressed by conducting pre-specified subgroup analyses (within the limits of power). While this is a useful approach for producing guidance to design and deliver the most effective interventions, subgroup analyses should be interpreted cautiously because other, uncontrolled differences between studies might account for the results.
Comparison with previous systematic reviews

Three existing systematic reviews examined the effectiveness of work stress interventions in healthcare professionals. Our findings about the effectiveness of burnout interventions and the likely superiority of organizational interventions are in agreement with the meta-analysis. In comparison, we narrowed our attention to controlled interventions and we undertook a number of evidence-based pre-specified subgroup analyses to examine whether the characteristics of interventions, physicians and healthcare settings influence the overall effect of burnout interventions. This decision was based on the recognition that controlled interventions offer the best opportunity to reach rigorous conclusions about the effectiveness of the tested interventions and that intervention studies on physician burnout are highly heterogeneous. This approach enabled us to draw informative conclusions for the effectiveness of burnout interventions among physicians which take into account the influence of the distinct features of interventions, physicians and healthcare settings.

Implications for researchers, clinicians and policymakers

Even though many studies have examined risk factors for burnout in physicians, relatively few intervention programs have been developed and evaluated. Our main finding is that the treatment effects were significant but small, equal to a 3-point reduction in the emotional exhaustion domain of the MBI. At present, the low quality of the research evidence does not allow firm practical recommendations but we offer some insights for research and clinical directions.

Organization-directed interventions were more likely to lead to reductions in burnout but there were large variations in terms actual approaches, intervention ingredients and intensity. Those which combined several elements such as structural changes, fostering
communication between members of the healthcare teams and cultivating a sense of teamwork and job control tended to be the most effective in reducing burnout. However, such intense organization-directed interventions were rare and were not evaluated widely. The majority of organization-directed interventions, which we included in the analyses, introduced simple reductions in the workload or schedule. Concerns around implementation and delivery costs of organization-directed interventions, especially if they involve complex and major healthcare system changes, might explain their scarcity. A recent example promoting healthy individual-organization relationships is the Listen-Act-Develop model implemented in Mayo Clinic. Large-scale cluster-randomized trials of such programs at institutional or even at national level which emphasize organizational culture by creating a safe space for staff to acknowledge and decrease stress are possibly an optimal framework for mitigating burnout.

Physician-directed interventions led to marginally significant and very small reductions in burnout. We found no evidence that the content (e.g. mindfulness, communicational, educational components) or intensity of these interventions might increase the derived benefits based on our critical review. This finding in combination with the larger effects of organization-directed interventions, support the argument that burnout is rooted in the organizational coherence of the healthcare system. If burnout is a problem of whole healthcare systems it is less likely to be effectively minimized by solely intervening at the individual level. It requires an organization-embedded approach. Moreover, physicians expected to deal with burnout individually and remotely from their practicing organization might view physician-directed interventions as a personal responsibility (or blame themselves for being less ‘resilient’) rather than as a shared resource to create a flourishing healthcare environment. There is some evidence that elements of the physician-directed interventions (e.g. mindfulness) are effective when supported by organizational
However, other unexamined factors at the process of the intervention delivery or at participant level might account for the observed differences in the effectiveness of organization-directed and physician-directed interventions. Research programs to understand the best context for the delivery, evaluation and the implementation of burnout interventions are required.\textsuperscript{71-73}

Physicians based in different healthcare settings or at different stages of their career might face unique challenges and have different needs. We found smaller benefits for recently qualified and secondary care physicians. The evidence indicates that young physicians are at higher risk for burnout compared to experienced physicians,\textsuperscript{5} so future research should focus on prevention among less experienced physicians. Interventions focused on enhancing teamwork, mentoring and leadership skills might be particularly suitable for young physicians and for physicians dealing with intense work and complex patients.\textsuperscript{74-76}

**Conclusion**

This meta-analysis found that physicians can gain important benefits from interventions to reduce burnout, especially from organization-directed interventions. However, this evidence is derived from interventions developed and evaluated in diverse groups of physicians and healthcare settings. Burnout is associated with serious risks to both physicians and patients, thus it is imperative that physicians have access to evidence-based interventions that reduce the risk for burnout.
