ABSTRACT

We studied the molecular gas properties of AzTEC/C159, a star-forming disk galaxy at $z = 4.567$, in order to better constrain the nature of the high-redshift end of the sub-mm selected galaxy (SMG) population. We secured $^{13}$CO molecular line detections for the J=2→1 and J=5→4 transitions using the Karl G. Jansky Very Large Array (VLA) and the NOrthern Extended Millimeter Array (NOEMA) interferometer. The broad (FWHM $\approx$ 750 km s$^{-1}$) and tentative double-peaked profiles of both $^{13}$CO lines are consistent with an extended gas reservoir, which is distributed in a rotating disk as previously revealed from [CII] 158 µm line observations. Based on the $^{13}$CO(2→1) emission line we derived a line brightness temperature ratio of $T_{b}(^{12}$CO)/$T_{b}(^{13}$CO) $\approx$ 3 (4 ± 0.6) x 10$^{10}$ K km s$^{-1}$ pc$^{-2}$, that yields a molecular gas mass of $M_\text{H}_2(\alpha_{^{12}\text{CO}}/4.3)$ = (1.5 ± 0.3) x 10$^{11}$ $M_\odot$, and unveils a gas-rich system with $\dot{M}_\text{gas}(\alpha_{^{13}\text{CO}}/4.3)$ = $M_\text{H}_2/M_\odot = 3.3 ± 0.7$. The extreme star formation efficiency (SFE) of AzTEC/C159, parametrized by the ratio $L_\text{IR}/L_{^{12}\text{CO}} = (216 ± 80)$ L$\odot$/K km s$^{-1}$ pc$^{-2}$, is comparable to merger-driven starbursts such as ultra-luminous infrared galaxies (ULIRGs) and SMGs. Likewise, the $^{13}$CO(5→4)/(^{13}$CO(2→1)) line brightness temperature ratio of $T_{b}(^{3}$CO)/$T_{b}(^{13}$CO) $\approx$ 0.5 ± 0.15 is consistent with high excitation conditions, similar to that observed in SMGs. Based on mass budget considerations we constrained the value for the $L_\text{CO}^{\text{star}} - H_\alpha$ mass conversion factor in AzTEC/C159, i.e. $\alpha_{^{12}\text{CO}} = 3.9^{+1.7}_{-1.0}$ $M_\odot$ K$^{-1}$ km$^{-1}$ s pc$^{-2}$, that is consistent with a self-gravitating molecular gas distribution as observed in local star-forming disk galaxies. Cold gas streams from cosmological filaments might be fueling a gravitationally unstable gas-rich disk in AzTEC/C159, which breaks into giant clumps forming stars as efficiently as in merger-driven systems and generate high gas excitation. These results support the evolutionary connection between AzTEC/C159-like systems and massive quiescent disk galaxies at $z < 2$.

Key words. galaxies: high-redshift – galaxies: formation – galaxies: ISM – ISM: molecules

1. Introduction

Sub-mm selected galaxies (SMGs), gas-rich starburst galaxies at high redshifts (e.g., Blain et al. 2002; Tacconi et al. 2006; 2008, 2010; Narayanan et al. 2010; Casey et al. 2014), might be the progenitors of compact quiescent galaxies (log($M_\star$/$M_\odot$) > 11) at $z$ = 2 (e.g., Simpson et al. 2014; Toft et al. 2014; Karashi et al. 2015) that eventually quench the star formation (Hopkins et al. 2006; Wuyts et al. 2010; Hickox et al. 2012; Steinhardt & Speagle 2014). However, there is a lack of consensus on the physical mechanisms driving the extreme production of stars in SMGs. It has been proposed that compact starbursts might be fueled via major gas-rich mergers (e.g., Walter et al. 2009; Narayanan et al. 2010; Hayward et al. 2011; Alaghband-Zadeh et al. 2012; Hayward et al. 2012; Riechers et al. 2013; 2014). An alternative scenario involves the smooth inflow and accretion of cold gas from the intergalactic medium that could also drive intense star formation in massive highly unstable high-redshift galaxies (e.g., Dekel et al. 2009a; Kereš et al. 2009b; Davé et al. 2010; Hodge et al. 2012; Romano-Díaz et al. 2014; Feng et al. 2015; Anglés-Alcázar et al. 2017). To constrain the origin of SMGs, and their possible evolutionary path, much effort has been put into building statistically complete and unbiased samples of these objects (e.g., Banerji et al. 2011; Yun et al. 2012; Hodge et al. 2013; Strandet et al. 2016; Brisbin et al. 2017; Michałowski et al. 2017). Particular emphasis has been placed on the recently discovered high-redshift tail ($4 < z < 6$) of the SMG population (e.g., Daddi et al. 2009a; b; Capak et al. 2008; 2011; Coppin et al. 2009; Knudsen et al. 2010; Smolčić et al. 2011; Barger et al. 2012; Walter et al. 2012; Livson et al. 2016). By exploring the physical properties of these $z > 4$ systems one might further strengthen the evolutionary link between high-redshift SMGs and massive quiescent galaxies at $z < 2$ (e.g., Fudamoto et al. 2017), and provide constraints on cosmological models that aim to reproduce the extreme and massive environments of early SMGs (e.g., Baugh et al. 2005; Dwek et al. 2011; Hayward et al. 2011; 2013; Ferrara et al. 2016). Probing the nature of these systems is, however, observationally expensive (e.g., Hodge et al. 2012) and somewhat complex. Although gravitationally lensed sources might overcome the issue of time-consuming follow-up observations (Strandet et al. 2016; Harrington et al. 2016; 2018) their derived quantities might be affected by lens modeling uncertainties (Büssmann et al. 2015).
To investigate the role of this relatively unexplored SMG population in the context of galaxy formation and evolution, Smolčić et al. (2015) have presented the largest set of spectroscopically confirmed and unlensed $z > 4$ SMGs (six sources) in the Cosmic Evolution Survey (COSMOS) field, where only AzTEC3 ($z = 5.298$) – studied in detail by Riechers et al. (2010, 2014) – was excluded. To explore the dust distribution and gas kinematics, high-resolution [CII] $158\mu$m line observations have been secured towards three of these sources; namely, J1000+0234 ($z = 4.544$), Vd−17871 ($z = 4.624$) and AzTEC/C159 ($z = 4.567$, Karim et al. in prep; hereafter K18). Based on these observations, Jones et al. (2017) hereafter J17 revealed a gas dominated rotating disk in J1000+0234 and AzTEC/C159. The latter emerges as the best example of a flat rotation curve at large radius. These extreme systems, with gas dominated rotating disks and concomitant intense star formation activity, seem to have no analog at lower redshifts; rendering their detailed study paramount to understand the formation of galaxies in the early Universe.

Here, we report the detection of $^{12}$CO(2→1) and $^{13}$CO(5→4) line emission to investigate the molecular gas properties of AzTEC/C159. $^{12}$CO observations have proved to be well suited to unveil the nature of the star-forming gas of high-redshift galaxies (e.g., Frayer et al. 1998, Riechers et al. 2008, Schinnerer et al. 2008, Carilli et al. 2010, Engel et al. 2010, Riechers et al. 2011, Hodge et al. 2012, Hodge et al. 2013, Bothwell et al. 2013, Bouché et al. 2013, Carilli & Walter 2013, De Breuck et al. 2014, Sánchez Almeida et al. 2014, Leroy et al. 2015, Narayanan et al. 2015). Low-$J$ $^{12}$CO emission lines provide tight constraints on the mass and extent of the molecular gas reservoir, as well as the star formation efficiency (SFE). In combination with multiple high-$J$ $^{12}$CO line detections, it is possible to explore the $^{12}$CO spectral line energy distribution (SLED) and unveil the physical properties of the star-forming gas (e.g., Weiss et al. 2005, Weiss et al. 2007, Carilli et al. 2010, Riechers et al. 2010, Papadopoulos et al. 2012b, Daddi et al. 2015). While the $^{12}$CO(2→1) and $^{13}$CO(5→4) line detections alone cannot fully constrain the shape of the $^{12}$CO SLED of AzTEC/C159, they do allow us to estimate the brightness temperature ratio $T_b$ (e.g., Bothwell et al. 2013). This parameter can be used to obtain initial insights about the overall excitation conditions of the molecular gas in high-redshift systems (e.g., Riechers et al. 2010). Molecular line spectroscopic studies, on the other hand, can be well complemented with FIR photometric information tracing the dust obscured star-formation activity in SMGs; via FIR SED fitting it is possible to estimate dust mass, infrared luminosity ($L_{IR}$) and hence star formation rates (SFR, e.g. Swinbank et al. 2014).

After introducing AzTEC/C159 in Section 2, we present the details of the observations in Section 3, followed by the results and discussion in Section 4 and 5. A summary is given in Section 6. Throughout, we assume the following cosmology $h_0 = 0.7$, $\Omega_M = 0.3$, and $\Omega_{\Lambda} = 0.7$.

2. AzTEC/C159

AzTEC/C159 was originally detected at the 3.7$\sigma$ level in the ASte/AzTEC-COSMOS 1.1 mm survey of the inner COSMOS 1 deg$^2$ (Aretxaga et al. 2011). Long-slit spectroscopy with DEIMOS/Keck has revealed a narrow Ly$\alpha$ line, which puts AzTEC/C159 at a redshift $z = 4.569$ (Smolčić et al. 2015). The broadband spectral energy distribution (SED) from the optical through the FIR is consistent with a dusty star-forming galaxy, with a star formation rate (SFR) of $\sim 700$ M$_\odot$/yr$^{-1}$, stellar mass of $(4.5 \pm 0.4) \times 10^{10}$ M$_\odot$ and dust mass of $2.0^{+13}_{-12}$ M$_\odot$ (Smolčić et al. 2015). Gómez-Guijarro et al. submitted; hereafter GG18). High-resolution [CII] $158\mu$m line observations (FWHM = 0.36 arcsec) with the Atacama Large Millimeter/submillimeter Array (ALMA; project 2012.1.00978.S, PI: A. Karim) have revealed a double horn profile, while the [CII] $158\mu$m first moment and channel maps are well described by the classic pattern for rotating disks (J17, K18). AzTEC/C159 complements the sample of galaxies at $z > 4$ exhibiting regular gas rotation on kpc-scales (i.e. disks); GN20 ($z = 4.50$, ALESS731 ($z = 4.755$), J1000+0234 ($z = 4.542$), Vd−17871 ($z = 4.622$), and J1319+0950 ($z = 6.127$; Hodge et al. 2012, De Breuck et al. 2014, Jones et al. 2017, Shao et al. 2017, K18). The kinematic signatures of rotation revealed by ALMA (J17, K18), including evidence of a flat rotation curve at large radius (J17), renders AzTEC/C159 one of the best examples to date for an apparently rotating disk galaxy in the early Universe. We note, however, that given the achieved $\sim 2.3$ kpc resolution ALMA observations we can not completely rule out a merging scenario from the [CII] line dynamical analysis alone. In this context, studies that probe the physical properties of the ISM, e.g. molecular gas, are also key to indirectly probe the dominant mode of star-formation in this system.

3. Karl G. Jansky VLA and NOEMA Observations

$^{12}$CO(2→1) line observations were carried out in January 2016 with the Karl G. Jansky Very Large Array (VLA) of the NRAO in the D- and DnC-configurations (project 15B-280; PI: A. Karim). Five observing sessions, 3.5 hrs each, resulted in a total of 17.5 hrs – with 9.0 hrs on target. We used the quasars 3C286 for bandpass, delay, and flux calibration, and J1038+0512 for complex gain calibration. We made use of the Q-band receivers and the pair of 8-bit samplers on each VLA antenna, resulting in a pair of 1.024 GHz bands in right and left circular polarization. These bands were overlapped by 128 MHz to correct for the loss of signal at their edges, so the total bandwidth was 1.92 GHz (from 40.963 to 42.883 GHz); covering the redshifted $^{12}$CO(2→1) line at 41.41 GHz, according to the prior redshift estimation of $z = 4.567 \pm 0.002$ based on the [CII] $158\mu$m line detection with ALMA (K18). Data were calibrated using the Common Astronomy Software Applications (CASA). Images were created with the CASA task clean and using a range of robust parameters. Ultimately, we use the image computed with robust=1 as it provides us with the best balance between spatial resolution and rms noise. This results in a data cube with a synthesized beam size of $1.70 \times 1.24$ arcsec resolution (PA = $77.5\degree$) with an rms of 0.05 mJy beam$^{-1}$ for 27 MHz ($\sim 200$ km s$^{-1}$) wide channels.

The $^{12}$CO(5→4) line was observed with the NONorthern Extended Millimeter Array (NOEMA) interferometer on December 8, 2015 and January 19, 2016 over two tracks (project 15CXX001, PI: A. Karim) in D- and C-configuration. We used the WideX correlator covering a frequency range of 3.6 GHz. The tuning frequency of 103.51 GHz was chosen to encompass the redshifted $^{12}$CO(5→4) line, considering $z = 4.567 \pm 0.002$. We used the quasars 3C84 and B0906+015 as flux and phase/amplitude calibrators, respectively. The data calibration and mapping were performed with the IRAM GILDAS software packages clean and mapping. The final cube corresponds to
4. Analysis and Results

4.1. CO lines

The $^{12}$CO(2→1) and $^{12}$CO(5→4) integrated lines are detected at the 5.5 and 8.1σ level, respectively. Fig. 1 shows the intensity maps integrated over $\pm 1500 \text{ km s}^{-1}$ where significant line emission was detected. The peak position of the $^{12}$CO lines spatially coincides with that of the [CII] 158 μm line (K18) within the positional uncertainties of $\pm 0.2$ and 0.5 arcsec, respectively. The $^{12}$CO(2→1) line spectrum was extracted within an ellipse of 2.1 $\times$ 1.7 arcsec (PA=90 degs). This aperture contains the total extent of the [CII] 158 μm line emission ($\sim$7 kpc; J17, K18) and assures that no flux is missed. We fit Gaussians to the $^{12}$CO line spectra within $\pm 850 \text{ km s}^{-1}$ of the centroid (see Fig. 1) and measure a FWHM of 750 km s$^{-1}$ for both lines. The line emission of $^{12}$CO(2→1) is centered at 41.425 $\pm$ 0.02 GHz, giving $z = 4.565 \pm 0.003$; while the $^{12}$CO(5→4) centroid at 103.550 $\pm$ 0.05 GHz yields $z = 4.565 \pm 0.003$. These values are in agreement with the redshift derived from the [CII] 158 μm line of 4.567 $\pm$ 0.002 (K18). Finally, we measure an integrated flux of 105 $\pm$ 19 mJy km s$^{-1}$ for the $^{12}$CO(2→1) line and 417 $\pm$ 51 mJy km s$^{-1}$ for $^{12}$CO(5→4). We verify that the latter values differ by less than 6% from those derived by adding individual flux densities per channel, within the velocity range used in the Gaussian fit.

The measured $^{12}$CO integrated line flux of high-redshift galaxies is influenced by the CMB emission. While the higher temperature of the CMB at $z = 4.5$ enhances the line excitation, the background against which the $^{12}$CO lines are measured also increases (e.g. da Cunha et al. 2013). For example, in a dense ISM ($n_H = 10^{22} \text{cm}^{-2}$), with a gas kinetic temperature of $T_{\text{kin}} = 40 \text{ K}$, we can measure 70% and 80% of the intrinsic

---

Fig. 1. (Upper panels) The velocity-integrated intensity maps of the $^{12}$CO(2→1) and $^{12}$CO(5→4) line. We integrated emission within the velocity range of $\pm 750 \text{ km s}^{-1}$, i.e. $\sim 8$ channels, where significant line emission was detected. The contour levels of the $^{12}$CO(2→1) line emission map are at [-2, 2, 3, 4]×1σ, with $\sigma = 0.05 \text{ mJy beam}^{-1}$ per 200 km s$^{-1}$ wide channel. Negative contours are shown in white and positives in blue. The beam size of 1.70 $\times$ 1.70 arcsec is plotted on the bottom left corner. The blue cross denotes the peak position of the [CII] 158 μm emission line. In the right panel we show the velocity-integrated intensity map of the $^{12}$CO(5→4) line emission. Contour levels are at [-3, 3, 4, 5, 6]×1σ, with $\sigma = 0.13 \text{ mJy beam}^{-1}$ per 200 km s$^{-1}$ wide channel. The beam size of 5.0 $\times$ 2.6 arcsec is also plotted on the bottom left corner. (Lower panels) The $^{12}$CO(2→1) and $^{12}$CO(5→4) line spectra binned to 200 km s$^{-1}$ channels. The red-solid lines are Gaussian fits to the line spectra, the central position is shown by the red-dashed lines. The blue error bar denotes the typical 1σ rms value.
value of the $^{12}\text{CO}(2\rightarrow1)$ and $^{12}\text{CO}(5\rightarrow4)$ line, respectively. In low density environments ($n_{H_2} = 10^{1.2}\text{cm}^{-3}$) with $T_{\text{kin}} = 18\text{K}$ only 20% of the intrinsic value of the $^{12}\text{CO}(2\rightarrow1)$ line is detected, and less than that for $^{12}\text{CO}(5\rightarrow4)$ (da Cunha et al., 2013). Unfortunately, we lack estimates for the gas density and kinetic temperature in AzTEC/C159. Yet, it is known that high SFR is likely to be associated with high temperatures of gas and dust as well as gas density (e.g., Narayanan & Krumholz 2014). Under the assumption of thermodynamic equilibrium between the gas and dust, we would have $T_{\text{gas}} = T_{\text{dust}} = 37\text{K}$ (from our mid-IR-mm SED fitting presented in Section 4.4). Therefore, we favor the scenario with dense gas and $T_{\text{gas}} = 40\text{K}$ that yields an increase in $S_{^{12}\text{CO}(2\rightarrow1)}$ and $S_{^{10}\text{CO}(3\rightarrow2)}$ by a factor $[1/0.7]$ and $[1/0.8]$, respectively (da Cunha et al., 2013). Consequently, we derive $S_{^{12}\text{CO}(2\rightarrow1)}^{\text{intrinsic}} = 150 \pm 27\text{mJy km s}^{-1}$ and $S_{^{12}\text{CO}(5\rightarrow4)}^{\text{intrinsic}} = 521 \pm 64\text{mJy km s}^{-1}$.

In Fig. 2, we compare the $^{12}\text{CO}$ and [CII] 158 µm line profiles. We find that the $^{12}\text{CO}$ lines are as broad as the [CII] 158 µm line (J17, K18), all with FWHM $\sim 750\text{ km s}^{-1}$. There is also marginal evidence of double-horn profiles in both $^{12}\text{CO}$ lines, where two peaks are close/above the 3σ level. To constrain the size of the $^{12}\text{CO}(2\rightarrow1)$ line emitting region we fit a single Gaussian model to the uv data and find evidence for a compact/point-like structure. Based on the synthesized beam size and SNR of the line detection, we use the results from Martí-Vidal et al. (2012) Eq. 7) to estimate an upper limit of $\sim 6.5\text{ kpc}$ at the redshift of AzTEC/C159. The presence of an extended and possibly rotating molecular gas reservoir would be consistent with the [CII] 158 µm gas extent ($\sim 7\text{ kpc}$) and dynamics of AzTEC/C159 (J17, K18). Yet, we advise caution when interpreting our results on the $^{12}\text{CO}$ size and dynamics of AzTEC/C159 due to the current limitation of our $^{12}\text{CO}$ line observations.

### 4.2. FIR properties

Continuum emission from AzTEC/C159 was detected at 3 mm from our NOEMA observations. By averaging line-free channel maps, around the $^{12}\text{CO}(5\rightarrow4)$ centroid at 103.550 GHz, we derive a value of $220 \pm 40\mu\text{Jy}$. No continuum emission was detected in our VLA observations at $\sim 7\text{ mm}$; based on the noise level of the continuum image, we derive a 3σ upper limit of $20\mu\text{Jy}$. These new mm data points mitigate the uncertainties in determining the FIR properties of AzTEC/C159.

We derive the infrared luminosity ($L_{\text{IR}}$; in the range $8\rightarrow1000\mu\text{m}$), SFR and dust mass ($M_{\text{dust}}$) of AzTEC/C159 via mid-IR-mm SED fitting using the Draine & Li (2007) dust model. We refer the reader to Smolčić et al. (2015) for a detailed description of the fitting process. As shown in Fig. 3, aside from our mm SED constraints, the 1.1 mm data point from the JCMT/AzTEC 1.1 mm survey (Scott et al., 2008) and ALMA 870 µm continuum data point (GG18), we use observations from the Herschel Space Observatory (Pilbratt et al., 2010) towards the COSMOS field: those from the Photodetector Array Camera and Spectrometer (PACS at 100 and 160 µm; Lutz et al., 2011) as well as the Spectral and Photometric Imaging Receiver (SPIRE at 250, 350 and 500 µm; Oliver et al., 2012). We find $L_{\text{IR}} = 7.4^{+21}_{-11}\times10^{12}\text{L}_\odot$, $T_{\text{dust}} = 37 \pm 3\text{K}$, $M_{\text{dust}} = 2.5^{+0.5}_{-0.3}\times10^{6}\text{M}_\odot$; by assuming a Chabrier IMF and the relation SFR [$M_\odot\text{yr}^{-1}] = 10^{-10}L_{\text{IR}}[\text{L}_\odot]$ (Kennicutt, 1998), we estimate a SFR $= 740^{+210}_{-170}\text{M}_\odot\text{yr}^{-1}$. The derived $L_{\text{IR}}$ and $T_{\text{dust}}$ are 0.3 dex and 5 K larger, respectively, than the characteristic values for the full ALESS SMG sample with a median redshift of $\sim 2.5$ (Swinbank et al., 2014). Similar to the $z > 4$ SMGs presented by Smolčić et al. (2015), AzTEC/C159 lies at the high-end of the $L_{\text{IR}} - T_{\text{dust}}$ correlation (e.g., Chapman et al., 2005; Magnelli et al., 2012), consistent with an extrapolation of the trend for Herschel-selected $0.1 < z < 2$ infrared galaxies (Symeonidis et al., 2013).

### 4.3. Molecular gas mass and SFE

The molecular gas mass can be estimated from the relation:

$$M_{\text{H}_2} = \alpha_{\text{CO}} L_{\text{CO}}^\prime,$$

where $\alpha_{\text{CO}}$ is the CO luminosity to H$_2$ mass conversion factor and $L_{\text{CO}}^\prime$ is the $^{12}\text{CO}(1\rightarrow0)$ line luminosity. The latter can be derived from our $^{12}\text{CO}(2\rightarrow1)$ line assuming that $L_{\text{CO}} = 1.18^2 L_{\text{CO}(2\rightarrow1)}$ for typical SMG excitation conditions (consistent with the results in Section 4.4) and using the relation (Carilli & Walter, 2013):

$$L_{\text{CO}(2\rightarrow1)} = 3.25 \times 10^{7} S_{\text{CO}(2\rightarrow1)} v_{\text{CO}(2\rightarrow1)}^2 D_L^2 (1+z)^{-1},$$

where $S_{\text{CO}(2\rightarrow1)}$ is the integrated line flux in Jy\text{ km s}^{-1}, $v_{\text{CO}(2\rightarrow1)}$ is the rest-frame frequency of the $^{12}\text{CO}(2\rightarrow1)$ line in GHz and $D_L$ the luminosity distance in Mpc. Based on $S_{\text{intrinsic}}\text{CO}(2\rightarrow1)$ (i.e. the corrected value from the CMB) and Eq. 2, we derive $L_{\text{CO}} = (3.4 \pm 0.6) \times 10^{10}\text{K km s}^{-1}\text{pc}^2$.

**Fig. 3.** Broadband SED of AzTEC/C159. The best fit Draine & Li (2007) model is shown by the blue dashed line. A modified blackbody (red line) is used to fit the FIR-to-mm data points. The monochromatic flux densities in the fit are listed as follows: \(S_{100\mu m} < 6.8\) mJy, \(S_{160\mu m} < 13.6\) mJy, \(S_{250\mu m} = 6.2 \pm 1.9\) mJy, \(S_{350\mu m} < 10.8\) mJy, \(S_{500\mu m} < 20.4\) mJy and \(S_{850\mu m} = 3.3 \pm 1.3\) mJy (Smolčić et al. 2013). We add three more sub-mm/mm data points from our observations: \(S_{370\mu m} = 6.9 \pm 0.2\) mJy (GG18), \(S_{350\mu m} = 220 \pm 40\) μJy and \(S_{1.1\text{mm}} < 20\) μJy. The downward pointing arrows denote upper limits to the corresponding flux densities.

The value for \(\alpha_{\text{CO}}\) depends on local interstellar medium (ISM) conditions and, consequently, may vary across different galaxy types (Daddi et al. 2010; Papadopoulos et al. 2012b; Magnelli et al. 2012; Bolatto et al. 2013). According to Papadopoulos et al. (2012b), the major driver of the \(\alpha_{\text{CO}}\) value is the average dynamical state of the molecular gas. As a result, while low values for \(\alpha_{\text{CO}}\) could be related to highly turbulent molecular gas – likely associated with merging systems – as observed in local ultra-luminous infrared galaxies (ULIRGs) with \(\alpha_{\text{CO}} = 0.8\) M\(_{\odot}\) K\(^{-1}\) km\(^{-1}\) s\(^{-1}\) pc\(^{-2}\) (e.g., Downes & Solomon 1998), self-gravitating gas yields high \(\alpha_{\text{CO}}\) values (e.g., Papadopoulos et al. 2012a) as in star-forming spiral disks like the Milky-Way with \(\alpha_{\text{CO}} = 4.3\) M\(_{\odot}\) K\(^{-1}\) km\(^{-1}\) s\(^{-1}\) pc\(^{-2}\) (e.g., Abdo et al. 2010). Spatially resolved observations of nearby SFGs have also probed that \(\alpha_{\text{CO}}\) might vary within the galaxy itself, where central values could be significantly smaller than the galaxy average (Sandstrom et al. 2013). For high-redshift unresolved sources, on the other hand, we have to rely on an average \(\alpha_{\text{CO}}\) that reflects the overall physical conditions of the molecular gas. Since J17 and K18 have revealed a rotationally supported gas disk in AzTEC/C159, it is likely that the bulk of the molecular gas is in self-gravitating clouds, pointing towards a Milky-Way-like \(\alpha_{\text{CO}}\) value. We discuss in more detail the nature of \(\alpha_{\text{CO}}\) in this source and validate this assumption in Section 4.5. By adopting \(\alpha_{\text{CO}} = 4.3\) M\(_{\odot}\) K\(^{-1}\) km\(^{-1}\) s\(^{-1}\) pc\(^{-2}\) we find \(M_{\text{H}_2} = (1.5 \pm 0.3) \times 10^{11}\) M\(_{\odot}\). Together with the stellar mass of AzTEC/C159 of \(M_{\star} = (4.5 \pm 0.4) \times 10^{10}\) M\(_{\odot}\) (GG18), we estimate a gas fraction of \(\mu_{\text{gas}} = M_{\text{H}_2}/M_{\star} = 3.3 \pm 0.7\) that is five times larger than the median for Main Sequence (MS) galaxies at \(z \sim 3\) (Schinnerer et al. 2016). It should be noted that even when assuming a ULIRG-like \(\alpha_{\text{CO}}\) Prescription (and a CMB uncorrected \(S_{\text{CO(2\rightarrow1)}}\) flux), the gas fraction would be high, i.e. \(0.43 \pm 0.10\). The massive molecular gas reservoir of AzTEC/C159 is consistent with the general picture of having...
large cool-ISM reservoirs fueling intense star formation activity at high redshift (e.g., Carilli & Walter 2013).

We use the empirical ratio $L_{\text{IR}}/L_{\text{CO}}$ as a proxy of the SFE of AzTEC/C159, allowing a more direct comparison with the average SFE of different galaxy populations. Based on the information in Table 1, we derive $L_{\text{IR}}/L_{\text{CO}} = (216 \pm 80) L_\odot (\text{K km s}^{-1} \text{pc}^{-2})^{-1}$, placing it within the upper scatter of the $L_{\text{IR}}/L_{\text{CO}}$ correlation as presented by Carilli & Walter (2013). This ratio is much higher than that observed in normal star-forming disk galaxies such as nearby spirals and at $(z \sim 0.4-2)$ MS galaxies (between 20 and 100 $L_\odot (\text{K km s}^{-1} \text{pc}^{-2})^{-1}$; Daddi et al. 2010, Magnelli et al. 2012), but comparable to merger-driven starbursts such as local ULIRGs and SMGs (e.g., Genzel et al. 2010; Bothwell et al. 2013, Aravena et al. 2016, and references therein). The SFE of AzTEC/C159 is, however, similar to those of the very high-redshift starburst disk galaxies GN20 ($\sim 180 L_\odot (\text{K km s}^{-1} \text{pc}^{-2})^{-1}$; Carilli et al. 2010, Hodge et al. 2012), and J1000+0234 ($\sim 140 L_\odot (\text{K km s}^{-1} \text{pc}^{-2})^{-1}$; Schinnerer et al. 2008, Smolčić et al. 2015). Thus, while the extreme SFE of AzTEC/C159 seems unusual for a star-forming disk galaxy at $z < 2$, at $z > 4$ disk galaxies harboring vigorous SFE (like AzTEC/C159, GN20 and J1000+0234) might be common.

### 4.4. Gas excitation

We combine the $^{12}$CO(2→1) and $^{12}$CO(5→4) line detections to obtain insights into the molecular gas excitation in AzTEC/C159. As mentioned before, at $z \sim 4.5$ the CMB emission affects the observed $^{12}$CO line flux density in both lines (da Cunha et al. 2013). This could modify the $^{12}$CO(5→4)/$^{12}$CO(2→1) line brightness temperature ratio ($r_{52}$) and, in consequence, our interpretation. Let us first consider the observed line flux densities in AzTEC/C159 and compare its $^{12}$CO SLED with those of the SMGs, as well as a robust mass-metallicity relation at such high redshift, we assume that AzTEC/C159 has solar metallicity. Then, by combining Eq. 3 and Eq. 4 to

$$\alpha_{\text{CO}} = \frac{\delta_{\text{GDR}} M_{\text{dust}}}{L'_{\text{CO}}},$$

where $\delta_{\text{GDR}}$ is the gas-to-dust ratio relation constrained locally by Leroy et al. (2010) that varies with metallicity as $\log(\delta_{\text{GDR}}) = 9.4 - 0.85 \times [12 + \log(O/H)]$. In the absence of direct metallicity estimates for AzTEC/C159, as well as a robust mass-metallicity relation at such high redshift, we assume that AzTEC/C159 has solar metallicity. Then, by combining Eq. 3 and Eq. 4 to

$$\alpha_{\text{CO}} = \frac{\delta_{\text{GDR}} M_{\text{dust}}}{L'_{\text{CO}}},$$

where $\delta_{\text{GDR}}$ is the gas-to-dust ratio relation constrained locally by Leroy et al. (2010) that varies with metallicity as $\log(\delta_{\text{GDR}}) = 9.4 - 0.85 \times [12 + \log(O/H)]$. In the absence of direct metallicity estimates for AzTEC/C159, as well as a robust mass-metallicity relation at such high redshift, we assume that AzTEC/C159 has solar metallicity. Then, by combining Eq. 3 and Eq. 4 to

$$\alpha_{\text{CO}} = \frac{\delta_{\text{GDR}} M_{\text{dust}}}{L'_{\text{CO}}},$$

In Section 4.1 we favored a scenario with dense gas and $T_{\text{kin}} = 40$ K to correct the observed $L'_{\text{CO}}$ by the effect of the CMB. Here, we also explore the possibility of having cool ($T_{\text{kin}} = 14$ K) and low-density molecular gas, i.e. according to da Cunha et al. (2013) we vary $L'_{\text{CO}}$ within the range $[3.4 \pm 0.6, 12.0 \pm 2.2] \times 10^{10}$ K km s$^{-1}$ pc$^{-2}$. Based on $M_{\text{dust}} = 2.5 \times 10^{6} M_\odot$ (derived in Section 4.2) and Eq. 4, we estimate $\alpha_{\text{CO}} = 3.8 \pm 0.3 M_\odot K^{-1} \text{km}^{-1} \text{s} \text{pc}^{-2}$. Note that a lower value of $\delta_{\text{GDR}}$ could lower the estimated $\alpha_{\text{CO}}$, but it would require unlikely supra-solar metallicity. On the contrary, sub-solar metallicities would yield even higher $\alpha_{\text{CO}}$.

### 4.5. The CO→H$_2$ conversion factor

By determining the $\alpha_{\text{CO}}$ value in AzTEC/C159, we can mitigate uncertainties on our gas mass estimates and, at the same time, infer the overall physical conditions of its molecular gas (e.g., Papadopoulos et al. 2012a,b). Here, we constrain $\alpha_{\text{CO}}$ from (a) the gas-to-dust ratio ($\delta_{\text{GDR}}$) and (b) the balance between the baryonic and dark matter content with the dynamical mass.

#### 4.5.1. The gas-to-dust method

By assuming that the molecular component dominates the ISM, i.e. $M_\text{H} \gg M_\text{HI} + M_\text{DM}$, the molecular gas mass can be estimated from the relation (e.g., Magnelli et al. 2012, Aravena et al. 2016):

$$M_{\text{gas}} = M_\text{H} = \delta_{\text{GDR}} M_{\text{dust}},$$

where $\delta_{\text{GDR}}$ is the gas-to-dust ratio relation constrained locally by Leroy et al. (2010) that varies with metallicity as $\log(\delta_{\text{GDR}}) = 9.4 - 0.85 \times [12 + \log(O/H)]$. In the absence of direct metallicity estimates for AzTEC/C159, as well as a robust mass-metallicity relation at such high redshift, we assume that AzTEC/C159 has solar metallicity. Then, by combining Eq. 3 and Eq. 4 to

$$\alpha_{\text{CO}} = \frac{\delta_{\text{GDR}} M_{\text{dust}}}{L'_{\text{CO}}},$$

In Section 4.1 we favored a scenario with dense gas and $T_{\text{kin}} = 40$ K to correct the observed $L'_{\text{CO}}$ by the effect of the CMB. Here, we also explore the possibility of having cool ($T_{\text{kin}} = 14$ K) and low-density molecular gas, i.e. according to da Cunha et al. (2013) we vary $L'_{\text{CO}}$ within the range $[3.4 \pm 0.6, 12.0 \pm 2.2] \times 10^{10}$ K km s$^{-1}$ pc$^{-2}$. Based on $M_{\text{dust}} = 2.5 \times 10^{6} M_\odot$ (derived in Section 4.2) and Eq. 4, we estimate $\alpha_{\text{CO}} = 3.8 \pm 0.3 M_\odot K^{-1} \text{km}^{-1} \text{s} \text{pc}^{-2}$. Note that a lower value of $\delta_{\text{GDR}}$ could lower the estimated $\alpha_{\text{CO}}$, but it would require unlikely supra-solar metallicity. On the contrary, sub-solar metallicities would yield even higher $\alpha_{\text{CO}}$.

Another approach to constrain $\alpha_{\text{CO}}$ is based on the estimation of the mass content, which should match the baryonic and dark matter content, i.e. $M_{\text{dyn}} = M_{\text{ISM}} + M_\star + M_{\text{DM}}$. Since we assume that the ISM is dominated by molecular gas, then $M_{\text{ISM}} \approx M_\text{H}$. This, in combination with Eq. 1 leads to:

$$\alpha_{\text{CO}} = \frac{M_{\text{dyn}} - M_\star - M_{\text{DM}}}{L'_{\text{CO}}}.$$

The [CII] 158$\mu$m gas dynamics of AzTEC/C159 has been characterized in detail by J17. Via the tilted ring fitting method they find that at an intrinsic radius of 2.9 kpc $M_{\text{dyn}} = (2.8 \pm 1.1) \times 10^{11} M_\odot$. This value agrees within the uncertainties with the value derived by K18 ($M_{\text{dyn}} \sim 4 \times 10^{11} M_\odot$) using the software “3D-Barolo” and assuming an inclination angle of $\sim 30$ degrees as in J17. Within an aperture radius of 2.9 kpc, we find that $S_{\text{[CII]}_{158\mu m}} = 91 \pm 16$ mJy, which is $\sim 13\%$ lower than that derived from the aperture that contains the full emission line (see Section 4.1). Consequently, as in the gas-to-dust ratio method,
we consider $L'_{\text{CO}} \in [2.9 \pm 0.5, 10.5 \pm 1.9] \times 10^{10} \, \text{K} \, \text{km} \, \text{s}^{-1} \, \text{pc}^2$.

GG18 have estimated the stellar mass of AzTEC/C159 ($14.5 \pm 0.4 \times 10^{10} M_\odot$) using LePHARE (Arnouts et al. 1999, Illbert et al. 2006) and adopting the Bruzual & Charlot (2003) stellar population synthesis models, a Chabrier (2003) IMF, and an exponentially declining star formation history (SFH). For this purpose, a substantial optical/near-IR dataset was used by GG18: the $g$, $r$, $i$, $z$ and $y$ bands from the Subaru Hyper Suprime-Cam imaging (HSC, Tanaka et al. 2017), near-IR $J$, $H$ and $Ks$ bands from the UltraVISTA DRS survey (McCracken et al. 2012), and the mid-IR Spitzer/IRAC 3.6 and 4.5μm bands from the Spitzer Large Area Survey with Hyper-Suprime-Cam (SPLASH, Capak et al. in prep.).

As discussed in detail in GG18, this stellar mass estimate could be subject to a number of systematic uncertainties. For instance, if the stars formed in-situ, it is possible that a fraction of the stellar light is being obscured by the dust and, therefore, the stellar mass used here might be underestimated. GG18 have estimated the stellar mass fraction we might be missing by this effect using different prescriptions for the dust-to-stellar-mass ratio (DTS). By considering the ratio derived from simulations in (Popping et al. 2017) of log(DTS) = −1.8, the stellar mass would increase by $0.4$ dex; on the other hand, the median DTS ratio for local ULIRGs log(DTS) = −2.83 (Calura et al. 2017) yields an increment of $\sim 1$ dex. The original estimate for the stellar mass (combined with the SFR of 740 $M_\odot$ yr$^{-1}$) put AzTEC/C159 on the upper-end of the MS of SFGs at $z \sim 4.5$ as given by (Schreiber et al. 2015). An increase in stellar mass by $0.4$ dex would instead place AzTEC/C159 right on the MS of SFGs, while an increase by $\sim 1$ dex would lead to a very unlikely scenario in which AzTEC/C159 lies significantly below the MS. From this, we conclude that the stellar mass of AzTEC/C159 reported by GG18 might be underestimated by at most $0.4$ dex. By applying Eq. 5 and considering the original estimate for the stellar mass ($14.5 \pm 0.4 \times 10^{10} M_\odot$) from GG18, as well as a negligible dark matter component, we derive $a_{\text{CO}} = 3.9^{+2.7}_{-1.3} M_\odot \, \text{K} \, \text{km} \, \text{s}^{-1} \, \text{pc}^2$. The addition of a $0.4$ dex factor in the stellar mass (i.e, $1.0 \pm 0.4 \times 10^{11} M_\odot$) still yields a relatively high $a_{\text{CO}}$ value of $2.7^{+1.2}_{-0.8} M_\odot \, \text{K} \, \text{km} \, \text{s}^{-1} \, \text{pc}^2$.

Our two independent methods point towards a high value of $a_{\text{CO}}$. This result agrees well with our previous assumption of $a_{\text{CO}} \sim 4.3 M_\odot \, \text{K} \, \text{km} \, \text{s}^{-1} \, \text{pc}^{-2}$. It is known that the most important influencing factor on $a_{\text{CO}}$ is the average dynamical state of the molecular gas. While low values are associated with unbound gas, as observed in local ULIRGs, high values are related with self-gravitating gas (e.g., Papadopoulos et al. 2012); hence, the molecular gas dynamics in AzTEC/C159 might be more similar to that of local star-forming disks than those of disturbed major mergers.

---

1. High spatial resolution rest-frame UV/optical/IR observations are required to map the dust and stellar light distribution and better constrain the stellar mass of AzTEC/C159. This would also allow one to explore the presence of multiple interacting components (and not a massive single component) that might fit into a merger-driven star formation scenario.

2. A highly conservative error bar for $M_{\text{dyn}}$ of 1 dex has been suggested by J17 to take into account systematic uncertainties of the method; i.e. $M_{\text{dyn}} = (2.8^{+1.1}_{-1.0}) \times 10^{11} M_\odot$. This large range for $M_{\text{dyn}}$ also affords a wider range of inclination angles. We derive $a_{\text{CO}} = 6.7^{+6.3}_{-4.9} M_\odot \, \text{K} \, \text{km} \, \text{s}^{-1} \, \text{pc}^{-2}$. Thus, what remains true is that $a_{\text{CO}}$ is still higher than the prescription for ULIRGs-like systems ($a_{\text{CO}} = 0.8 M_\odot \, \text{K} \, \text{km} \, \text{s}^{-1} \, \text{pc}^{-2}$).
5. Discussion

Molecular line observations towards AzTEC/C159 reveal a gas-rich system, elevated SFE, and high gas excitation. Its high $\alpha_{\text{CO}}$ value is consistent with a self-gravitating molecular gas distribution (e.g., Papadopoulos et al. [2012a]). In addition, [CII] 158 $\mu$m line observations have already revealed a gas dominated rotating disk extending up to a radius of $\sim$3 kpc (J17). These dynamical properties do not fit into the scenario of gas-rich galaxy mergers at high redshift driving tidal torques that form dense gas regions (a condition for high gas excitation) and trigger intense star formation activity (e.g., Hopkins et al. [2006]; Hayward et al. [2011, 2012]). Then, the question arises as to what would be the physical mechanisms responsible for fueling and triggering such extreme star formation environment in this gas-rich rotating disk galaxy at $z = 4.5$.

According to numerical simulations, massive rotating disk galaxies in the early Universe are not a rare phenomenon (e.g., Dekel et al. [2009b]; Romano-Díaz et al. [2011]). In overdense environments, the smooth infall and accretion of cold gas from cosmological filaments can build up a disk (Peng et al. [2015]). This relatively smooth accretion, which dominates the mass input (Romano-Díaz et al. [2014]; Anglés-Alcázar et al. [2017]), can maintain an unstable dense gas-rich disk that breaks into giant clumps forming stars at a high rate (Dekel et al. [2009b]). Such star formation activity might be enhanced due to gravitational harassment, as advocated for the star-forming disk galaxy at $z = 4.05$ GN20 (Carilli et al. [2010]; Hodge et al. [2012]).

The latter scenario agrees with the high gas fraction and SFE of AzTEC/C159, but it is at odds with the high gas excitation condition usually associated with major-mergers (e.g., Bournaud et al. [2015]). However, as predicted by Papadopoulos et al. [2012a], high-redshift disk-like systems with extreme SFE – like AzTEC/C159 – could also have high gas excitation conditions as a result of heating by turbulence and/or cosmic rays. In fact, by $z \sim 3$ the mean radiation field intensity (U) in MS galaxies might become similar to that of local ULIRGs and their $^{12}$CO SLEDs may look similar at this redshift (Daddi et al. [2015]). We note that an elevated $^{12}$CO SLED could be also a result of AGN-driven mechanical and radiative feedback (Papadopoulos et al. [2008, 2010]; Dasyra et al. [2014]; Moser et al. [2016]); however, there is no robust evidence of an AGN in AzTEC/C159 (Smolčić et al. [2015]).

It is difficult to draw a coherent conclusion on galaxy formation and evolution from this source alone. Nevertheless, AzTEC/C159 emerges as another gas-rich galaxy at $z \sim 4$ with high SFE and extreme $^{12}$CO SLED: together with J1000+0234 (Schinnerer et al. [2008, 2017]) and GN20 (Carilli et al. [2010]; Hodge et al. [2012]). This galaxy population complements our picture on galaxy evolution. In particular, Toft et al. (2017) suggest that such $z > 4$ SMGs with cool gas reservoirs distributed in rotating disks, and high SFE, might be the progenitors of massive quenched galaxies at $z \sim 2$ that – surprisingly – also exhibit a rotating disk (van der Wel et al. [2011]; Newman et al. [2015]). To confirm this, we need to exploit the synergy between ALMA and the upcoming JWST, that promise a better understanding of the multi-phase gas and stellar properties of early systems.

6. Summary

We reported the molecular gas properties of the star-forming disk galaxy AzTEC/C159 at $z = 4.367$. By using $^{12}$CO line observations of the transition levels J=2→1 and J=5→4, and extensive ancillary data from the COSMOS collaboration, we have found that:

1. The molecular gas mass of AzTEC/C159 is $M_{\text{mol}}$($^{12}$CO/4,3) $= (1.5 \pm 0.3) \times 10^{11} M_{\odot}$, which yields a high gas fraction of $\mu_{\text{gas}}$($^{12}$CO/4,3) $= M_{\text{gas}}/M_{\odot} = 3.3 \pm 0.7$. Its $L_{\text{IR}}/L_{\text{CO}}$ ratio of $(216 \pm 80) L_{\odot}$ ($K \text{ km s}^{-1} \text{pc}^2$)$^{-1}$, i.e. SFE, is comparable with that of local ULIRGs and SMGs (e.g., Aravena et al. [2016] and references therein).

2. The $^{12}$CO lines show tentative evidence of a double-peak line profile. Their FWHM is comparable to that of the [CII] 158 $\mu$m line (FWHM $\sim 750 \text{ km s}^{-1}$; J17, K18), that is consistent with an extended gas reservoir. However, the modest sensitivity and resolution of our observations prevent us from obtaining definitive constraints on the $^{12}$CO extent and dynamics of AzTEC/C159.

3. The $^{12}$CO(5-4)/$^{12}$CO(2-1) line brightness temperature ratio of $T_{\text{B}} = 0.55 \pm 0.15$ is consistent with the high gas excitation of the star-forming disk galaxies GN20 (Carilli et al. [2010]; Hodge et al. [2012]) and J1000+0234 (Schinnerer et al. [2008, 2017]) at $z > 4$. In general, the $^{12}$CO SLED of AzTEC/C159 is similar to the median for SMGs (Bothwell et al. [2013]) and significantly deviates from that for star-forming disk galaxies at $z \sim 1.5$ (Daddi et al. [2015]).

4. The CO$\rightarrow$H$_2$ conversion factor ($\alpha_{\text{CO}}$) for AzTEC/C159 is $3.9^{+2.7}_{-1.3} M_{\odot} \text{K}^{-1} \text{ km}^{-1} \text{ s}^{-2}$ and $3.85^{+3.8}_{-1.4} M_{\odot} \text{K}^{-1} \text{ km}^{-1} \text{ s}^{-2}$, as given by the dynamical and gas-to-dust method, respectively. This suggests that the conditions of the ISM in AzTEC/C159 would be consistent with those of local star-forming disks.

The intense star formation activity of AzTEC/C159 does not seem to be triggered by major mergers as other SMGs. Instead, its molecular gas conditions suggest that cold gas streams may fuel a gravitationally unstable gas-rich disk, that harbors extreme SFE and high gas excitation. A population of high-redshift disk galaxies has been predicted by both numerical simulations and recent observational studies of quiescent rotating disk galaxies at $z \sim 2$, that are believed to be the descendants of AzTEC/C159-like galaxies.
