Received 5 March 2002/Accepted 18 June 2002

In response to ionizing radiation (IR), the tumor suppressor p53 is stabilized and promotes either cell cycle arrest or apoptosis. Chk2 activated by IR contributes to this stabilization, possibly by direct phosphorylation. Like p53, Chk2 is mutated in patients with Li-Fraumeni syndrome. Since the ataxia telangiectasia mutated (ATM) gene is required for IR-induced activation of Chk2, it has been assumed that ATM and Chk2 act in a linear pathway leading to p53 activation. To clarify the role of Chk2 in tumorigenesis, we generated gene-targeted Chk2-deficient mice. Unlike ATM−/− and p53−/− mice, Chk2−/− mice do not spontaneously develop tumors, although Chk2 does suppress 7,12-dimethylbenzanthracene-induced skin tumors. Tissues from Chk2−/− mice, including those from the thymus, central nervous system, fibroblasts, epidermis, and hair follicles, show significant defects in IR-induced apoptosis or impaired G1/S arrest. Quantitative comparison of the G1/S checkpoint, apoptosis, and expression of p53 proteins in Chk2−/− versus ATM−/− thymocytes suggested that Chk2 can regulate p53-dependent apoptosis in an ATM-independent manner. IR-induced apoptosis was restored in Chk2−/− thymocytes by reintroduction of the wild-type Chk2 gene but not by a Chk2 gene in which the sites phosphorylated by ATM and ataxia telangiectasia and rad3+ related (ATR) were mutated to alanine. ATR may thus selectively contribute to p53-mediated apoptosis. These data indicate that distinct pathways regulate the activation of p53 leading to cell cycle arrest or apoptosis.

DNA damage activates cellular responses that promote DNA repair, arrest the cell cycle, and in some cases, induce apoptosis (56). Cell cycle arrest allows time for the repair of damaged DNA while apoptosis eliminates cells harboring abnormal DNA. It is widely believed that these DNA damage responses are required for the maintenance of genomic stability and prevention of tumor development (20).

The ataxia telangiectasia (A-T) mutated (ATM) gene, which is homologous to the yeast checkpoint gene Tel1, plays a critical role in sensing DNA double strand breaks (DSBs) in mammalian DNA. ATM is a kinase involved in activating the appropriate damage response pathway, leading to either cell cycle arrest or apoptosis, and is therefore a key checkpoint molecule in regulating cell cycle responses to DNA damage (37, 45). Indeed, the majority of phosphorylation events induced by ionizing radiation (IR) are carried out by ATM. Both A-T patients and ATM-deficient mice show defective cell cycle arrest, hypersensitivity to DNA DSBs, and tumor predisposition (4, 21, 52, 53). When cells are damaged by IR, ATM phosphorylates and activates the protein kinase Chk2 (1, 35, 36, 55). Chk2 is a homologue of the rad53 gene in budding yeast and of the Cds1 gene in fission yeast. Once phosphorylated, activated Chk2 phosphorylates multiple Cdc25 molecules which are thought to inhibit the activation of cyclin-dependent kinases (7, 10, 34). However, in response to damage induced by UV-irradiation or hydroxyurea, Chk2 is phosphorylated in an ATM-independent manner, possibly by A-T and rad3+ related (ATR) (35, 46). Notably, ATM, ATR, and Chk2 are each able to phosphorylate the tumor suppressor gene p53 (2, 9, 11, 26, 42, 49).

p53 is the most frequently mutated cancer-associated gene identified to date (29). In response to DNA damage, p53 undergoes phosphorylation and conformational changes which result in increased levels and activity of the protein (23). Increased p53 activity enhances the rate of transcription of numerous target genes (such as p21, Mdm2, GADD45, and Bax) that mediate the plethora of p53-dependent functions (19, 54). These functions include the promotion of apoptosis and the induction of G1 cell cycle arrest. The p53 protein can be mod-
ified by many different protein kinases and acetylases, resulting in modulation of p53 function (39). In particular, the phosho dephosphorylation of various serine residues can have a significant impact on p53 stability. Recent studies with phoshop-specific antibodies have established that serines (Ser) 6, 9, 15, 20, 33, 37, and 46 of p53 are sites of de novo phosphorylation in cells following DNA damage and that phosphorylation of different sites has different effects (2, 9, 12, 25, 38, 43, 44, 47). For example, it has been proposed that the phosphorylation of the N-terminal Ser 15, 33, and 37 residues permits subsequent modification of the distant C-terminal ly-sine residues of p53 through enhanced recruitment of the co-activator protein p300/CBP/PCAF (28, 41). In contrast, phosphylation of Ser20 is required for stability of p53 in response to DNA damage (11). Ser20 comprises part of the site used by Mdm2 to bind p53 and target it for ubiquitination, and phosphorylation of Ser20 interferes with Mdm2 binding. Previous studies have demonstrated that, in response to IR, Ser15 on p53 is phosphorylated by ATM (2, 9), whereas Ser20 is phosphorylated by Chk2 (11, 26, 42). There is abundant evidence that ATM controls p53 stabilization either directly or indirectly via Chk2, and it is also now clear that p53-mediated G1 arrest is suppressed in ATM−/− thymocytes. However, it is more controversial whether ATM is involved in p53-mediated apoptosis of damaged cells. While some laboratories have shown that ATM−/− thymocytes are resistant to IR-induced apoptosis (51, 53), others have found that these cells exhibit normal p53-mediated cell death (3, 21, 24). It appears that the pathways governing p53-dependent cell cycle arrest and apo- ptosis may be distinct and that ATM plays a major role in regulating only the former.

Previous work on Chk2-deficient thymocytes reconstituted from Chk2−/− embryonic stem (ES) cells in Rag1−/− mice showed that Chk2 contributes to p53 stabilization following exposure to IR (26). We have now created mutant mice in which the Chk2 gene was disrupted through homologous recombination. We report on the phenotype of Chk2−/− mice and compare it to that of ATM−/− mice. Using various Chk2−/− cell types, we show that Chk2 is involved in both ATM-dependent and ATM-independent regulation of IR-in- duced p53-mediated apoptosis.

MATERIALS AND METHODS

Generation of Chk2−/− mice. To generate Chk2−/− mice, fragments of the murine Chk2 gene were isolated from a mouse 129 genomic library by using the mouse Chk2 cDNA as a probe. The targeting construct was designed to delete the exons encoding the conserved kinase sequence as described previously (26). ES clones heterozygous for the targeted mutation were isolated by drug selection and confirmed by Southern blotting. Two independent heterozygous ES clones were injected into 3.5-day C57BL/6 blastocysts which were subsequently transferred into pseudopregnant foster mothers. Chimeric mice were crossed into pseudopregnant foster mothers. Chimeric mice were injected into 3.5-day C57BL/6 blastocysts which were subsequently trans- formed to generate Chk2−/− mice. The thymus and skin from the dorsal area were perfused with ice-cold saline followed by fixation in ice-cold 4% paraformalde- hyde. The brains were removed and fixed for a further 24 to 48 h in 4% paraformaldehyde at 4°C. The thymus and skin from the dorsal area were fixed in 10% buffered formalin overnight at 4°C. Tissue samples were embedded in wax for following standard sectioning at a thickness of 5 to 7 μm. Apoptosis is thymus, skin, and brain sections was analyzed by the terminal deoxynucleotidyltransferase-mediated dUTP nick end labeling (TUNEL) assay (Boehringer-Mannheim). Sectioned material was prepared for the TUNEL assay by following standard procedures (33). Briefly, sections were deparaffinized and rehydrated through a graded series of ethanol solutions to phosphate-buffered saline. Sections were then subjected to the TUNEL assay. To quantify the apoptosis of thymocytes in vitro, thymocytes were isolated from 5- to 8-week-old mice and irradiated with 1 to 4 Gy of irradiation. Apoptotic cells were detected by flow cytometric analysis with Annexin V and propidium iodide (PI) staining (R&D Systems).

Cell cycle analysis. For analysis of G1 arrest in the skin, P7 mice were irradiated with 5 Gy of irradiation, and the mice were injected intraperitoneally with bromodeoxyuridine (BrDU) (1 mg) 1 h before sacrifice (48). Skin sections were treated with 3% hydrogen peroxide for 15 min to quench endogenous perox- idase. BrDU was detected by using a BrdU staining kit (Oncoexpression Research Products) according to the manufacturer’s protocol. For analysis of the G0/S checkpoint in the thymus, 5- to 8-week-old mice were irradiated with 10 Gy of irradiation and injected with 2 mg of BrDU at 2 h postirradiation (3). At 1 h postinjection, the mice were sacrificed and the thymus were dissected. Thymocytes were fixed by using the BrdU flow kit (BD Pharmingen). The fixed cells were treated with 300 μg of DNase/ml for 1 h at 37°C and then incubated with anti-BrDU-fluorescein isothiocyanate for 30 min at room temperature. After washing, the cells were counterstained with PI and subjected to flow cytometry. To detect mitotic cells, skin sections were incubated with anti-phosphohistone H3 antibody (Ab) (Upstate Biotechnology). After incubation with secondary Ab followed by Vectastain ABC reagents, the slides were exposed to DAB substrate (Vector Laboratories). Total cell numbers and the number of BrDU- or phos- phohistone H3-positive cells were counted in several regions of the epidermis of each mouse.

G1 arrest was examined in cultured mouse embryonic fibroblasts (MEFs) established as described previously (18). MEFs were synchronized at G0 by irradiation for 4 days in Dulbecco’s minimal essential medium containing 0.1% serum. The G0-synchronized cells were trypsinized and resuspended in growth medium containing 65 μM BrDU. The cells were irradiated with 0 to 20 Gy of irradiation, replated, and cultured for 24 h prior to fixation in 70% ethanol. Cells were then stained with anti-BrDU Ab (BD Pharmingen) as described previously. To evaluate the S-phase checkpoint, the inhibition of DNA synthesis was mea- sured by using a previously described procedure (27). Briefly, exponentially growing MEFs were irradiated with 10 Gy of irradiation and cultured for 0 to 3 h. [3H]thymidine (2.5 μCi/ml) was added 30 min prior to sampling. Cells were lysed in 0.5 ml of 2% sodium dodecyl sulfate (SDS) in 0.2 M NaOH, and 100 μl of lysis was added onto Whatman 17 CHR paper. The filters were washed with 5% trichloroacetic acid, rinsed in 95% ethanol, and air dried, and the incorpo- rated radioactivity was measured in a liquid scintillation counter.

Northern blotting. Thymocytes were subjected to 5 Gy of γ-irradiation, and total RNA was isolated by using Trizol according to the manufacturer’s protocol (GIBCO BRL). Briefly, thymocytes (2 × 10⁶) were lysed with 1 ml of Trizol and mixed with chloroform. Total RNA was precipitated with isopropl alcohol, and 5 μg/sample was electrophoresed on a 1% agarose gel followed by transfer to a membrane (GeneScreen plus; NEN Life Science Products). Blots were hybrid- ized with mouse p21, Bax, and β-actin cDNA probes, and the intensity of each band was quantified by densitometry (Storm680; Molecular Dynamics). Statis- tical analyses were carried out by using Student’s t test.

Western blotting. Tissues were lysed in lysis buffer (10 mM Tris-HCl [pH 7.5], 10 mM KCL, 2 mM MgCl₂, 1 mM dithiothreitol, 5 mM Na₂P₂O₇, 1 μM NaN₃, and 50 mM NaF plus protease inhibitor cocktail [Boehringer Mannheim]). Ly- sates were boiled with SDS sample buffer at 100°C for 5 min and placed on ice. Protein extracts were fractionated by SDS–10% polyacrylamide gel electro- phoresis and transferred to a polyvinylidene difluoride membrane (Sigma). The blot was incubated with 4% milk overnight followed by incubation with anti-p53 Ab (CM5; Novocastra Laboratories), anti-mouse Chk2 Ab (26), or anti-β-actin Ab (Sigma). Signals were visualized by incubation with horseradish peroxidase-conjugated secondary Ab (Amersham) followed by enhanced chemiluminescence (Amersham).

Flow cytometric analysis. The preparation of samples for flow cytometry was performed as described previously (26). Cells were analyzed on a Becton Dick- inson FACScan (Becton-Dickinson, Mountain View, CA). DNA flow to tumor formation. The backs of 6- to 8-week-old mice were shaved and painted with 10 μg of 7,12-dimethylbenzanthracene (DMBA) (Sigma) in 0.2 ml of acetone once a week for 25 weeks. Scoring for tumors was done once a week.
Chk2, somatic chimeras were generated by Rag1 cloning into pCAGGS. To obtain thymocytes expressing wild-type or mutant Chk2 to Ala-Gln (AQ) followed by sub
tagenesis was used to change the seven Ser-Gln/Thr-Gln (SQ/TQ) sites (Ser 22,
versity with a blunt end. To create the mutated Chk2 allele, PCR-based mu-
Chk2 cDNA was cloned into pCAGGS (a gift of Junichi Miyazaki, Osaka Uni-
of the coding region of the mouse Chk2 cDNA by PCR. The full-length mouse
pgk-Hygro into Chk2
Chk2,or the empty vector was electrophoretically transfected along with pBS-
ubiquitously expressed in wild-type mouse tissues with its high-
est levels in the thymus, spleen, and colon (Fig. 1B). The protein was not detected in Chk2−/− tissues, confirming the null mutation.

Chk2 is not essential for somatic growth, fertility, or immunological development. Since Chk2 activation in response to DNA DSBs is dependent on ATM (34), we anticipated that Chk2−/− mice might display overlapping phenotypes with those of ATM−/− mice. We therefore investigated several of the most obvious phenotypes of ATM−/− mice in Chk2−/− animals.

ATM−/− mice are smaller in size and weigh less than their wild-type or heterozygous littermates (4, 21, 52). However, Chk2−/− mice were not smaller than control mice at birth, at weaning, or through adulthood (male, +/+ versus +/− versus −/−: 19.5 ± 3.4 g versus 23.1 ± 2.1 g versus 22.0 ± 2.6 g, respectively; female, +/+ versus +/− versus −/−: 18.2 ± 3.2 g versus 17.8 ± 1.3 g versus 17.9 ± 3.1 g, respectively) (42 days of age). In addition, while cultured MEFs from ATM−/− mice showed extremely poor growth consistent with the animals’ growth retardation, cultured Chk2−/− fibroblasts did not show an obvious growth deficit (data not shown).

ATM−/− mice are infertile due to a defect in germ cell development. However, Chk2−/− male and female mice are fertile, and their gonads are histologically normal (data not shown).

Several immunological abnormalities have been reported in ATM−/− mice, including a defect in T-lymphocyte maturation. However, lymphoid tissues from Chk2−/− mice were similar in gross size to those of their Chk2+/− and wild-type littermates, and no histological abnormalities were observed in the thymus, spleen, or lymph nodes. The numbers of thymocytes and spleen cells isolated from Chk2−/− mice were comparable to those of the controls at 8 to 10 weeks of age. Analysis of cell surface markers of isolated Chk2+/− lymphoid cells showed that populations of cells bearing CD3, CD4, CD8, Thy1, or T-cell receptor αβ were not affected by the loss of Chk2 in either the thymus or the spleen. The development of immature T cells, as evaluated by CD25 and CD44 expression, was also normal. Analysis of the expression of B220, immunoglobulin D (IgD), IgM, and CD43 in spleen and bone marrow cells revealed no abnormalities in B-cell development. The proliferation of peripheral lymph node T cells stimulated with anti-CD3 Ab, anti-CD28 Ab, and interleukin-2 was normal, as was that of splenic B cells stimulated with anti-CD40 Ab, anti-IgM Ab, interleukin-4, or lipopolysaccharide. Immunoglobulin levels in Chk2−/− mice were normal.

Apoptosis and cell cycle arrest induced by IR are defective in Chk2−/− mice. In our previous work, we showed that CD4+ CD8+ thymocytes isolated from Chk2−/− Rag1−/− chimeric animals were resistant to IR-induced apoptosis because of a lack of p53 stabilization. In this study, we evaluated the role of Chk2 in regulating IR-induced cell death in vivo. Wild-type and Chk2−/− mice were subjected to whole-body γ-irradiation, and their thymic tissues were evaluated for apoptosis by using the TUNEL assay. Thymi of unirradiated wild-type and Chk2−/− mice showed very few apoptotic cells (Fig. 2A). As expected, substantial apoptosis was observed in the thymi of irradiated wild-type mice. However, the thymi of irradiated Chk2−/− mice showed significantly less apoptosis. We next examined the effect of the Chk2 mutation on hair follicular

RESULTS

Generation of Chk2−/− mice. The Chk2 gene was disrupted by replacing a region of the genomic sequence containing exons 8 to 11 with a neomycin resistance cassette (Fig. 1A). Following transfection, selection of targeted clones, and blastoct microinjection, chimeric mice were produced that successfully transmitted the Chk2 mutation to the germ line. F1 heterozygote mice were intercrossed to generate animals homozygous for the mutant Chk2 allele. Chk2−/− mice were viable and born at the expected Mendelian ratio (+/+; +/+; −/− = 0.20:0.53:0.26). The expression of Chk2 protein was assessed in Chk2+/− and Chk2−/− mice. The Chk2 protein is ubiquitously expressed in wild-type mouse tissues with its high

FIG. 1. Targeted disruption of the Chk2 gene in mice. (A) Targeting strategy. The genomic configuration of the germ line Chk2 locus is shown at the top. The targeting vector is shown in the center; exons 8 to 11 were replaced with a neomycin cassette (Neo). The mutated Chk2 locus is shown at the bottom. (B) Western blot showing the expression of Chk2 and β-actin proteins in various tissues of wild-type (Wild) and Chk2−/− mice.
FIG. 2. Induction of apoptosis in response to γ-irradiation. (A) Mice (8 weeks old) were mock irradiated (a and b) or irradiated with 10 Gy of irradiation (c and d), and apoptosis in thymi was evaluated at 10 h post-IR. (B) Mice (P7) were mock irradiated (a and b) or irradiated with 5 Gy of irradiation (c and d), and apoptosis in skin was evaluated at 6 h post-IR by in situ TUNEL staining. E and F indicate epidermis and hair follicle, respectively. (C) Mice (P5) were mock irradiated (a and b) or irradiated with 10 Gy of irradiation (c and d), and apoptosis in the hippocampal dentate gyrus was evaluated at 24 h post-IR by in situ TUNEL staining. Arrows indicate apoptotic TUNEL-positive cells.
matrical cells since these cells have been shown to be susceptible to IR-induced apoptosis (4, 48). Four hours after 5 Gy of irradiation, a large number of cells in the wild-type matrix were undergoing apoptosis, as evaluated by an in situ TUNEL assay (Fig. 2B). In contrast, there was an almost complete absence of IR-induced apoptosis in the follicular matrices of Chk2/H11002/H11002 mice. Finally, we examined IR-induced apoptosis in the developing CNS. In wild-type perinatal mice (P5), significant apoptosis was observed in many regions of the CNS 24 h after 5 Gy of γ-irradiation, consistent with previous reports. Strikingly, very little apoptosis was observed in the CNS, including the cerebellum and dentate gyrus, of irradiated Chk2/H11002/H11002 mice (Fig. 2C and data not shown).

Since IR induces cell cycle arrest at several distinct cell cycle transitions, we studied the effect of the absence of Chk2 on the G1/S, S, and G2/M checkpoints. First, we examined the G1/S checkpoint in epidermal cells in vivo. P7 mice were irradiated with 5 Gy of irradiation followed by BrdU injection 1 h prior to sacrifice. The frequency of BrdU-positive cells in Chk2/H11002/H11002 epidermis was comparable to that in wild-type tissue (wild type versus Chk2/H11002/H11002: 108 ± 13 per 1,000 cells versus 110 ± 15 per 1,000 cells). Although epidermal cells are not susceptible to IR-induced apoptosis, there was a clear reduction in the BrdU-positive population in the wild type at 24 h postirradiation (21 ± 5 per 1,000 epidermal cells), likely due to the operation of the G1/S checkpoint (Fig. 3A). In contrast, there was no reduction in the BrdU-positive population at 24 h in either Chk2/H11002/H11002 epidermis (112 ± 10 per 1,000 cells) or in p53/H11002 epidermis (132 ± 7 per 1,000 cells). G1 arrest was also evaluated in cultured wild-type, p53/H11002, and Chk2/H11002 MEFs. Serum-starved cells were irradiated and stimulated to enter the cell cycle by the addition of serum. BrdU was added with the serum to allow the detection of S-phase entrance. In response to increasing doses of IR, p53/H11002 MEFs failed to arrest in G1, as expected (Fig. 3B) (18). Wild-type MEFs arrested normally in G1 as evidenced by a dose-dependent reduction in the number of BrdU-positive cells. Interestingly, Chk2/H11002 MEFs were significantly defective in their ability to arrest in G1 at low IR doses but behaved like wild-type cells at higher doses.

To examine the G2/M checkpoint, we used an anti-phospho-histone H3 Ab which specifically recognizes mitotic cells to evaluate the frequency of mitotic cells in the epidermis following IR. In the absence of IR, the frequency of mitotic cells was comparable in wild-type and Chk2/H11002/H11002 mice (wild type versus Chk2/H11002/H11002: 18 ± 4 per 1,000 cells versus 20 ± 4 per 1,000 cells) (Fig. 3C). Almost no mitotic cells were observed in wild-type or Chk2/H11002/H11002 mice 6 h after exposure to 5 Gy of irradiation, indicating that the induction of G2 arrest is intact in Chk2/H11002 mice. However, mitosis had resumed in Chk2/H11002/H11002 cells by 24 h post-IR (21 ± 4 per 1,000 cells), whereas wild-type cells still showed suppression of mitosis (3 ± 2 per 1,000 cells) at this time. These data indicate that the loss of Chk2 curtails the duration of the G2/M checkpoint.

An intra-S-phase checkpoint occurs in MEFs in response to IR, and this checkpoint requires ATM function (4). We evaluated the effect of the Chk2 mutation on this checkpoint by examining the inhibition of DNA synthesis in MEFs. Both wild-type and Chk2/H11002 primary MEFs showed equivalent levels of DNA synthesis inhibition following IR, whereas ATM/H11002 cells showed a characteristic profile of radiation-
resistant DNA synthesis (Fig. 3D). These findings show that the intra-S-phase checkpoint is ATM dependent but Chk2 independent.

**Incidence of DMBA-induced skin tumors is enhanced in Chk2-deficient mice.** Since the loss of Chk2 leads to suppressed apoptosis and cell cycle arrest in response to IR, one would expect to find a higher incidence of tumor formation in Chk2−/− mice, perhaps comparable to that in p53−/− mice. However, by age 1 year, Chk2−/− mice had not developed tumors of any kind. We speculate that tumors caused by the loss of Chk2 are either too rare to be detected or require a prolonged period to develop. We therefore challenged...
acertized in thymocytes, and it is possible to precisely quantify these phenotypes in this cell type. When wild-type mice were subjected to 10 Gy of γ-irradiation, the number of thymic BrdU-positive S-phase cells was reduced to 35% ± 4% of that in the nonirradiated controls (Fig. 5A). The G1/S-phase checkpoint was defective in ATM−/− and p53−/− mice (ATM−/−, 132% ± 10%; p53−/−, 128% ± 11%), consistent with previous reports (3). In contrast to irradiated ATM−/− mice, irradiated Chk2−/− mice showed only a partial defect that resulted in milder G1 arrest (65% ± 5%). However, when thymocytes were isolated from Chk2−/− mice and subjected to IR in vitro, apoptosis was dramatically impaired (Fig. 5B). ATM−/− thymocytes were more resistant than wild-type thymocytes to IR-induced apoptosis but considerably more sensitive than either Chk2−/− or p53−/− thymocytes. It should be noted that the IR-induced apoptosis and inhibition of the G1/S transition observed in this study are p53 dependent because they are completely inhibited by the loss of p53 function. Dying p53−/− thymocytes can be detected after 48 h of IR treatment, and irradiated Chk2−/− p53−/− thymocytes behave in the same manner as irradiated p53−/− cells (data not shown). These results indicate that Chk2 acts in the pathway leading to p53-dependent apoptosis rather than in the general apoptosis program.

Our findings led us to hypothesize that Chk2 selectively regulates p53 activity leading to apoptosis. To address this question, we used Northern blotting to evaluate the transcription of mRNA expression for known p53 target genes. Although the expression of many molecules is induced by p53 activation, p21 and Bax are the most prominent p53-responsive genes in mouse primary thymocytes (8). Loss of p21 in thymocytes leads to a clear defect of the G1 checkpoint induced by IR (18). Although Bax−/− thymocytes are not resistant to IR-induced apoptosis, Bax−/− Bax−/− thymocytes fail to die in response to IR (32). Since Bax−/− thymocytes also show normal responses to IR, the induction of Bax must be critical for IR-induced apoptosis. In wild-type thymocytes subjected to 5 Gy of IR, Bax mRNA was increased by (6.05 ± 1.44)-fold over the baseline at 3 h and by (5.68 ± 1.64)-fold at 6 h (Fig. 5C, left panel). Strikingly, irradiated Chk2−/− thymocytes showed defective induction of Bax ([1.9 ± 0.45]-fold at 3 h and [1.80 ± 0.40]-fold at 6 h). These results represent statistically significant decreases compared to the wild type at 3 h (P < 0.01) and 6 h (P < 0.01). In contrast, irradiated ATM−/− thymocytes were slower than the wild-type to induce Bax mRNA synthesis at 3 h (P < 0.05) but had caught up by 6 h. p21 mRNA induction was significantly suppressed compared to that of the wild type (P < 0.05) in both ATM−/− and Chk2−/− irradiated thymocytes at 3 h (Fig. 5C, right panel), but there were no significant differences in the level of suppression between these two genotypes. Consistent with a previous report (3), neither p21 nor Bax was induced in irradiated p53−/− thymocytes. These results suggest that thymic apoptosis induced by IR depends on p53 function and is controlled mainly by Chk2 rather than ATM. p53 was stabilized partially by IR in both ATM−/− and Chk2−/− thymocytes (Fig. 5D). Taken together, the data in Fig. 5 demonstrate that Chk2, rather than ATM, controls p53-mediated apoptosis, and that p53-mediated apoptosis does not correlate with stabilization of the p53 protein.

We next determined whether Chk2 phosphorylation is re-
quired for the activation of p53 leading to apoptosis. Mouse Chk2 has seven N-terminal SQ/TQ sites in the N-terminal region of the protein. In response to IR in vivo, ATM phosphorylates several of these SQ/TQ sites in Chk2, including Thr68 (1, 35, 36). Phosphorylation of Chk2 following IR is abolished by mutation of these SQ/TQ sites, and most of the endogenous Chk2 is not phosphorylated in ATM−/− cells (Fig. 5D); nevertheless, p53-mediated apoptosis can occur under these circumstances. To determine whether the phosphorylation of Chk2 SQ/TQ sites is required for Chk2-mediated regulation of p53-mediated apoptosis, we reintroduced into Chk2−/− thymocytes a mutant form of Chk2 in which all N-terminal SQ/TQ sites were replaced with AQ and analyzed apoptosis. In a previous study (35), the mutated SQ/TQ kinase had the same level of kinase activity as the wild-type enzyme when transfected into ATM−/− MEFS. To reintroduce the mutated Chk2 gene into Chk2−/− thymocytes, we generated somatic chimeras by Rag1−/− blastocyst complementation. An expression vector carrying wild-type or mutant Chk2 was transfected into Chk2−/− ES cells, and clones with

FIG. 5. IR-induced p53 activation and p53 stabilization in Chk2−/− and ATM−/− thymocytes. (A) G1/S checkpoint induced by γ-irradiation. The indicated strains of mice were irradiated with 10 Gy of irradiation and injected 1 h later with BrdU. At 2 h post-IR, thymocytes were isolated, stained with anti-BrdU Ab, and subjected to flow cytometry. Each value represents the mean percentage ± standard deviation (SD) of BrdU-positive (S phase) cells present after IR in 4 samples per group relative to the unirradiated controls. (B) Apoptosis induced by γ-irradiation. Isolated thymocytes were treated with the indicated doses of γ-irradiation, and apoptotic cells were evaluated by flow cytometry after Annexin V and PI staining. Each value represents the mean percentage ± SD of viable cells (Annexin V negative and PI negative) for 4 samples per group. (C) Induction of p53 downstream molecules. Total RNA was isolated from thymocytes before and after treatment with 5 Gy of irradiation. The expression of mRNA for p21, Bax, and β-actin was evaluated by Northern blotting. The amount of p21 or Bax mRNA was quantified by using a PhosphorImager analyzer and normalized to β-actin expression. Each value represents the mean increase (n-fold) ± SD of the expression of Bax or p21 mRNA after IR in 3 to 5 samples per group relative to the unirradiated controls. (D) p53 protein stabilization and Chk2 phosphorylation in thymocytes after irradiation. Isolated thymocytes were irradiated with 5 Gy of irradiation and lysed at the indicated times. p53 and Chk2 proteins were detected by Western blotting with anti-p53 or anti-Chk2 Ab. Wild, wild type.
DISCUSSION

We have shown in this study that there are differences between Chk2+/− and ATM+/− cells in the IR-induced activation of checkpoint and apoptotic responses, despite the fact that ATM regulates IR-induced Chk2 activity. ATM and Chk2 both modify p53 and activate it; however, our results show that at least some p53 phosphorylation is Chk2 dependent and ATM independent. Moreover, Chk2-dependent and ATM-dependent p53 phosphorylation events may differentially affect downstream p53-dependent transactivation targets. Specifically, we have demonstrated that Chk2 predominantly regulates IR-induced apoptosis rather than the G1/S checkpoint in thymocytes, whereas ATM is predominantly involved in the regulation of the G1/S checkpoint.

Contradictory results have been reported regarding the effect of ATM on p53-mediated apoptosis (3, 21, 24, 53). The discrepancies among these reports are not caused by strain differences among experimental mice but could be due to differences in methods used to detect apoptosis or to irradiation conditions (in vivo versus ex vivo). The in situ TUNEL assay may not be sensitive enough to detect differences in apoptosis in a thymus taken from an ATM+/− mouse treated with whole-body irradiation, whereas in vitro irradiation of isolated ATM+/− thymocytes reveals an apoptotic defect. In contrast, Chk2+/− thymocytes examined using either method show obvious resistance to IR-induced apoptosis. In our study, ATM+/− thymocytes were more resistant than the wild type to IR but significantly less resistant than Chk2+/− thymocytes. Consistent with the results of the apoptosis assay, the induction of Bax mRNA was more profoundly impaired in Chk2+/− thymocytes than in ATM+/− cells. This tight correlation between the induction of apoptosis and the transactivation of p53 downstream molecules suggests that the inhibition of apoptosis induced by the loss of Chk2 is caused by the suppression of p53 activation itself and not by effects on molecules further downstream in the apoptosis pathway.

We and others have proposed a model of IR-induced p53 activation in which Chk2 phosphorylates Ser20 of p53, leading to stabilization of p53 protein in an ATM-dependent manner (11, 26). Certainly, p53 stabilization was suppressed in both Chk2+/− and ATM+/− mice. However, the loss of ATM or Chk2 had different effects on p53 activation leading to apoptosis, indicating that the regulation of IR-induced p53 activation is not as simple as proposed above. Both ATM and Chk2 are required for p53 stabilization, but Chk2 must have another effect on p53 function in addition to stabilization that promotes apoptosis in response to IR (Fig. 7). Loss of Chk2 does lead to a defect of the G1/S checkpoint, but this could be caused by defective p53 protein stabilization. A similar explanation could hold for the partial effect of the ATM mutation on apoptosis.

The mechanism underlying the regulation of p53 activation remains unknown, but a key candidate is phosphorylation since p53 is phosphorylated on many sites in response to DNA damage. Regulation of p53 activation by Chk2 could involve the phosphorylation of additional sites on p53 or of other molecules that affect p53 activation. For example, the phosphorylation of Ser46 on p53 is specifically required for the induction of p53AIP1, a gene inducing apoptotic cell death. Mutation of Ser46 abolishes the ability of p53 to induce apo-
ptosis and selectively blocks transcription of p53AIP (but not other p53 target genes) (38). These data suggest that posttranslational modification of the p53 protein may determine its affinity for specific p53 binding sequences present in different target genes. Unfortunately, we do not know if Chk2 affects phosphorylation of Ser46 and p53AIP1 because Ser46 on human p53 is not conserved in mouse p53. It remains possible that other types of p53 modifications such as acetylation could lead to apoptosis via Chk2.

Mutation of the SQ/TQ sites on Chk2 abolished p53 activation leading to apoptosis, demonstrating that the phosphorylation of the SQ/TQ sites in the N-terminal region of Chk2 is essential for this process. Most of the phosphorylation of Chk2 induced by IR is abolished if ATM is absent. However, our data suggest that there is some ATM-independent phosphorylation at SQ/TQ sites of Chk2 in response to IR. It is possible that the very low level of ATM-independent phosphorylation of Chk2 that occurs is insufficient to alter the mobility of the protein. The most likely agent of ATM-independent Chk2 phosphorylation is ATR, although other members of the phosphatidylinositol 3-kinase family are also possibilities. ATR is a phosphatidylinositol 3-kinase-related kinase which contains a protein kinase domain similar in sequence to a region of Schizosaccharomyces pombe rad3 (6, 13). Matsuoka et al. have reported that ATR phosphorylates Thr26, Ser50, and Thr68 in the SQ/TQ cluster domain of human Chk2 in vitro (35). Although ATR is believed to act primarily in response to a DNA replication block or UV-irradiation, it is also involved in responses to IR. Cells lacking ATR die within several days of exposure to IR; however, prior to their deaths, a profound defect in the IR-induced G2/M checkpoint can be demonstrated (16). Other studies have shown that overexpression of a kinase-dead mutation of ATR causes increased sensitivity to IR and a defect in the G2/M arrest and S-phase checkpoints (14). Furthermore, ATR mutation also abolishes DNA damage-induced phosphorylation of Ser15 on p53 (49). These data suggest a potential functional overlap between ATM and ATR with respect to IR responses, consistent with our hypothesis that ATM and ATR cooperate in regulating p53 activity (Fig. 7). We theorize that ATR selectively regulates p53 activation leading to apoptosis via Chk2, while ATM governs cell cycle arrest in a Chk2-independent manner.

In addition to phosphorylating p53, Chk2 is known to phosphorylate Cdc25. It has been reported that ATM and Chk2 are required for the S-phase checkpoint induced by IR and that this induction depends on Chk2-dependent phosphorylation of Cdc25A (22). In our study, we confirm that ATM is required for the S-phase checkpoint in primary MEFs but we also demonstrate that Chk2 is dispensable for this checkpoint in this cell type. In experiments with immortalized MEFs, we have observed a slightly slower onset and shorter duration of the S-phase checkpoint in the absence of Chk2 (unpublished data). This small difference may reflect differences in cell cycle parameters between primary and transformed cells. On balance, however, we believe that Chk2 is not essential for S-phase arrest in normal cells. It is possible that Chk1 can substitute for Chk2 in the phosphorylation of Cdc25 and that Chk2 thus has a redundant function in the intra-S-phase checkpoint. Previous reports concluding that Chk2 was required for the intra-S-phase checkpoint utilized overexpression constructs containing mutated Chk2 genes identified in sporadic colon cancer and as a germ line mutation in Li-Fraumeni syndrome (LFS). The data showed that these mutations had a dominant-negative impact in wild-type cells. Constructs containing such mutations could therefore have an inhibitory effect on a downstream component of the S-phase checkpoint (such as Cdc25), thereby preventing the operation of any compensatory Chk1-dependent process. Alternatively, differences in Chk2 dependency in different tissues or between mice and humans may underlie the discrepancy between the previous reports and our data.

Failures in the transcriptional response to damage, cell cycle arrest and apoptosis induced by IR should lead to a higher incidence of tumor development. Unexpectedly, however, Chk2−/− mice do not have obvious tumors, unlike ATM−/− mice, which die within 4 months of birth with thymic lymphomas. Interestingly, the thymic lymphomas in ATM−/− mice are critically dependent on V(D)J recombination, whereas thymic lymphomas in p53−/− mice arise independent of V(D)J recombination (30). These observations indicate that at least two different mechanisms of lymphoma development are at work in these mutant animals, such that ATM-mediated p53 activation may not be required for the development of lymphomas. ATM phosphorylates many target substrates in addition to Chk2 and p53, including Nbs1 and Brca1 (17, 31). These molecules, which act downstream of ATM, may contribute in an unknown way to the prevention of spontaneous lymphoma development.

Mutations of Chk2 are found more frequently in patients with variant LFS, which has a moderate phenotype, than in patients with classical LFS (5). In contrast, mutations of p53 have been reported in 70% of classical LFS cases and 20% of variant LFS patients (50). Although the tumor-suppressive ef-
fect of Chk2 appears to be milder than that of p53, loss of Chk2 clearly increased the incidence of DMBA-induced skin tumors in mice. DBMA treatment resembles UV-irradiation in that both cause DNA adducts that are repaired by the nucleotide excision repair system. This similarity in DNA lesions suggests that the DMBA-induced skin tumors appearing in Chk2−/− mice could be the result of a failure in the tumor-suppressive effect by ATR.

In conclusion, the results of this study have shown that p53 activation leading to cell cycle arrest is regulated differently from that leading to apoptosis. Chk2 is required for p53-mediated apoptosis of thymocytes and must undergo phosphorylation in order to function, but this phosphorylation is not carried out by ATM. We propose a new model for the IR pathway that emphasizes the independent effects of Chk2 and ATM.

ACKNOWLEDGMENTS

We thank Malte Peters, Atsushi Togawa, and Katsuya Tsuchihara for helpful discussions, Peter J. McKinnon for providing ATM−/− mice, Junichi Miyazaki for providing pCAGGS, Mary Saunders for scientific editing, Denis Bouchard for technical expertise, and Irene Ng for excellent administrative support.
