(Received 1 July 2004; published 18 October 2004)

Detecting dark energy dynamics is the main quest of current dark energy research. Addressing the issue demands a fully consistent analysis of cosmic microwave background, large-scale structure, and SN-Ia data with multiparameter freedom valid for all redshifts. Here we undertake a ten parameter analysis of general dark energy confronted with the first year Wilkinson Microwave Anisotropy Probe, 2dF galaxy survey and latest SN-Ia data. Despite the huge freedom in dark energy dynamics there are no new degeneracies with standard cosmic parameters apart from a mild degeneracy between reionization and the redshift of acceleration, both of which effectively suppress small scale power. Breaking this degeneracy will help significantly in detecting dynamics, if it exists. Our best-fit model to the data has significant late-time evolution at $z < 1.5$. Phantom models are also considered and we find that the best-fit crosses $w = -1$ which, if confirmed, would be a clear signal for radically new physics. Treatment of such rapidly varying models requires careful integration of the dark energy density usually not implemented in standard codes, leading to crucial errors of up to 5%. Nevertheless cosmic variance means that standard cold dark matter models are still a very good fit to the data and evidence for dynamics is currently very weak. Independent tests of reionization or the epoch of acceleration (e.g., integrated Sachs-Wolfe–large scale structure correlations) or reduction of cosmic variance at large scales (e.g., cluster polarization at high redshift) may prove key in the hunt for dynamics.

DOI: 10.1103/PhysRevD.70.083006 PACS numbers: 98.70.Vc, 98.80.Es

I. INTRODUCTION

Cosmological observations suggest that the Universe is dominated by an exotic form of matter which is responsible for the present phase of accelerated expansion [1−4]. Several scenarios have been proposed to account for the observations, but the nature of this dark energy still remains unknown. The simplest minimal model to fit the experimental data assumes the presence of a cosmological constant, representing the vacuum energy contribution to the spatial curvature of the space-time. In spite of the success of this concordance $\Lambda$ cold dark matter ($\Lambda$CDM) model, there is no reasonable explanation why the observed value of $\Lambda$ is extremely small compared to particle physics expectations [5].

Alternatively, a light scalar field, called quintessence, rolling down a flat effective potential has been proposed to account for the missing energy in the Universe [6,7]. In particular quintessence models manifesting “tracker” properties allow the scalar field to dominate the present Universe independently of the initial conditions [8,9].

Different realizations of the original quintessence idea have been studied in the literature including the possibility of a scalar field evolution driven by a noncanonical kinetic term [10] and a nonminimal coupling between quintessence and dark matter [11−14]. On the other hand unified models of dark matter and dark energy have been considered [15−17]. Despite the proliferation of scalar field models of dark energy, we still lack of a fully consistent particle physics formulation. Nonetheless distinguishing between a dynamical form of dark energy and a cosmological constant is of immense importance as it would give us a hint on the nature of this component. The recent Wilkinson Microwave Anisotropy Probe (WMAP) satellite measurements of the cosmic microwave background (CMB), by providing an accurate determination of the anisotropy power spectrum, offer the opportunity to have a better insight into the physics of the dark energy. The quintessence hypothesis has been tested with different methods using pre-WMAP CMB data and SN-Ia data or the 2dF power spectrum [18−23]. These analysis have constrained the dark energy equation of state $w$ without ruling out the possibility of a time dependence. In this article we carry out an analysis of the time evolution of the dark energy equation of state. Our aim is to constrain a set of parameters characterizing the dark energy properties and the standard cosmological parameters by performing a likelihood analysis of the WMAP first year data [24] and the SN-Ia luminosity distance measurements [1,25]. The paper is organized as follows: in Sec. II and the Appendices we describe the method and the data, in Sec. III we explain the evaluation of the likelihood, in Sec. IV we discuss our results and finally in Sec. V we present our conclusions.
II. METHOD AND DATA

The most general way of constraining the time evolution of the dark energy equation of state would require us to consider a completely free function $w(z)$. As this corresponds to an infinite number of new degrees of freedom, we have to simplify the problem. We use a physically motivated parametrization where $w = p/\rho$ is defined by its present value, $w_0$, its value at high redshift, $w_m$, the value of the scale factor where $w$ changes between these two values, $a_t$, and the width of the transition, $\Delta$. Namely:

$$w(a) = w_0 + (w_m - w_0)\Gamma(a, a_t, \Delta)$$

where $\Gamma$, the transition function, has the limits $\Gamma(a = 0) = 1$ and $\Gamma(a = 1) = 0$ and varies smoothly between these two limits in a way that depends on the two parameters $a_t$ and $\Delta$ (see Fig. 1). Such a choice has been shown to allow adequate treatment of generic quintessence and to avoid the biasing problems inherent in assuming that $w$ is constant. Two choices for $\Gamma$ have been given in the literature [23,26] as discussed in Appendix A. Here we use the form advocated in [26].

Using this general prescription has a profound advantage in attempts to detect dark energy dynamics since, unlike simpler parametrizations based on only one or two variables, it can accurately describe both slowly and rapidly varying equation of states [27]. Detecting dark energy dynamics and distinguishing it from a cosmological constant is difficult and is clear only when there are rapid, late-time changes in $w$ [28], which then needs a formalism capable of describing such rapid transitions.

In order to compute the CMB power spectra, we use a modified version of the CMBfast Boltzmann solver [29].

This is a nontrivial step in the case where $\Gamma$ changes rapidly (such as in our best-fit model!). In fact using a numerical method that is not able to track rapid transitions can lead to errors significantly larger than the error bars on the data, of order 5%, and consequently lead to completely wrong results. Our tests are described in detail in Appendix B and C.

Several degeneracies amongst the cosmological parameters prevent us from accurately constraining cosmological models using CMB data only. Specific features of the anisotropy power spectrum can provide information on particular combinations of the cosmological parameters. For instance the relative height of the Doppler peaks depends on the baryon density and the scalar spectral index. In order to break such degeneracies it is necessary to add external information. Since our goal is to constrain the properties of the dark energy, in a flat geometry the main limitation comes from the geometric degeneracy between $w_0$, the dark energy density $\Omega_{DE}$ and the Hubble parameter $h$. This degeneracy can be broken by assuming an (Hubble space telescope) HST prior on the value of $h$ [30] and/or combining the CMB with other data sets such as the matter power spectrum measurements from the 2dF galaxy survey [31] or the SN-Ia data. In our analysis we use the “gold” subset of the recent compilation of supernova data of [25] in addition to the WMAP temperature (TT) and cross temperature polarization (TE) spectra. An important point which we want to stress here is that CMB and SN data can be treated at a fundamental level without any prior assumption on the underlying cosmological model. For instance, this is the case for the matter power spectrum data from galaxy surveys which implicitly assumes a $\Lambda$CDM model when passing from redshift space to real space. For this reason we add the 2dFGRS large-scale structure data only in order to check the stability of our results. We also remark that the use of secondary observables such as the age of the Universe, the size of the sound horizon at the decoupling, the clustering amplitude $\sigma_8$ (as quoted by the WMAP-team) or the growth factor of matter density perturbations should not be used without thought to infer constraints on the dark energy since their quoted value is usually derived by implicitly assuming a $\Lambda$CDM cosmology. This leads to biased results since these observables depend on the nature of the dark energy [28,32,33]. In principle CMB constraints can be easily added by using the position of the Doppler peaks, which provide an estimate of the angular diameter distance to the last scattering surface. But it is a well known fact that pre-recombination effects can shift the peaks from their true geometrical position [32].

The integrated Sachs-Wolfe (ISW) effect also induces an additional shift in the position of the first peak, in a way that is strongly dependent on the evolution of the dark energy equation of state and is generally larger than in $\Lambda$CDM models [28]. Therefore a consistent dark energy data analysis of the CMB indeed requires the computation of the CMB power spectrum (and TE cross correlation).
Each of our models is then characterized by the dark energy parameters \( W_{DE} = (w_0, w_a, a, \Delta) \) and the cosmological parameters \( W_c = (\Omega_{DE}, \Omega_b h^2, h, n_S, \tau, A_s) \), which are the dark energy density, the baryon density, the Hubble parameter, the scalar spectral index, the optical depth, and the overall amplitude of the fluctuations, respectively. We therefore end up with ten parameters which can be varied independently.

There is a remaining degeneracy in \( n_S, \tau \) and \( \Omega_b h^2 \), which allows the models to reach unphysically high values of the baryon density and the reionization optical depth. Following the WMAP analysis and in order to remain consistent with [34], we place a prior on the reionization optical depth, \( \tau \leq 0.3 \). An alternative is to use a prior on \( \Omega_b h^2 \), which may be physically better motivated and does a better job of breaking the degeneracy—we plan to use this for future work and discuss the difference later on. We also limit ourselves to models with \( w(\zeta) \approx -1 \), except where stated explicitly.

## III. EVALUATION OF THE LIKELIHOOD

A grid-based method would necessarily lead to a very coarse sampling, which is why we opted for a Markov chain Monte Carlo (MCMC) method to sample the likelihood surface. In addition this approach also allows easy marginalization over parameters. We ran 16 to 32 independent chains on the U.K. national cosmology supercomputer (COSMOS). This approach has both the advantage that there was no need to parallelize the Boltzmann solver, and that we are better able to assess correlations in several dimensions, which are the dark energy density, the baryon density, the Hubble parameter, the overall amplitude of the fluctuations, which are the dark energy density, the baryon density, the Hubble parameter, the scalar spectral index, the optical depth, and the overall amplitude of the fluctuations, respectively. We therefore end up with ten parameters which can be varied independently.

The result of a MCMC is a “cloud” of samples in each chain with a density proportional to the local value of the likelihood. In general we are not content with a \( N \)-dimensional description of the likelihood, but would prefer lower dimensional constraints. The generally accepted way to project the likelihood onto fewer dimensions is through marginalizing. This means that we integrate the likelihood over the parameters which we want to hide:

\[
L(p_1, \ldots, p_{i-1}, p_{i+1}, \ldots, p_n) \\
\approx \int dp_i L(p_1, \ldots, p_{i-1}, p_i, p_{i+1}, \ldots, p_n). \tag{3}
\]

This requires a measure \( \mu = dp \) on the parameter space. In many cases, there is some physical motivation for the choice of the measure. Alternatively, it may be that the for all reasonable choices, the measure does not vary strongly across the range of interest. As an example, we could use either \( \Omega_b \) or \( \Omega_b h^2 \) as a fundamental parameter. But since both \( H_0 \) and \( \Omega_b h^2 \) are quite well constrained, the result will not change appreciably if we use the one or the other. In this case, it does not matter which one we use. If neither is true then the result can depend strongly on the choice of this measure.

In the MCMC case, the choice of measure is implicit in the choice of parameters if one follows the usual rule that the marginalization is done by summing up the samples. To illustrate this, let us assume that the likelihood does not depend upon a given parameter \( 0.1 \leq p \leq 10 \). In this case, the marginalization over this parameter is just the volume of the parameter space, since all values are equally likely. The resulting likelihood will be flat, independent of the choice of parametrization. Using \( p \) as our fundamental parameter, we find that roughly half the points will be in \( p < 5 \) and half in \( p > 5 \). On the other hand, using \( \log p \) we will find that half the points are in \( p < 1 \), and half in \( p > 1 \). The result depends in this case strongly on the choice of parametrization. We would like to add here that a linear transformation of the parameters does not change the measure, as long as the boundaries of the integration are also adjusted. This is normally the case, since the integration volume is usually given by the region where \( L \neq 0 \). An example of such a transformation is the use of a covariance matrix to render the parameters linearly independent.

A different way to think about this specific problem is by looking at the choice of measure as a prior. Choosing for a parameter \( p \) the measure \( dp \) (i.e., sample it equally in \( p \)) is the same as imposing a flat prior, \( P(p) = 1 \). Instead, sampling the parameter in \( \log(p) \), corresponding...
to a measure $dp/p$, corresponds to a flat prior in $\log(p)$ or $P(p) = 1/p$ when sampling evenly in $p$ [39].

In order to test our dependence on the choice of parameterization, we ran chains for different choices, namely $(a_1, \Delta)$, $[\log(a_1), \Delta]$ and $[\log(a_1), \log(\Delta)]$. In the next section we will discuss which of the results depend on this choice.

A second issue which is often neglected is that the likelihood which we deal with here is by no means close to Gaussian in some of the variables. The structure of the minima can thus be arbitrarily complicated. It is therefore important to specifically search for the global minimum, which can of course be rather difficult in many dimensions.

As a final remark before discussing the results, we would like to point out that caution is necessary when interpreting the results. One sigma limits are not sufficient to rule out anything—the true model is indeed expected to lie about one sigma away from the expectation value! Even two sigma or 95% (the limits which we usually quote) are not sufficient. We present here limits and constraints on well over 20 different variables, and so we again expect at least one to lie in the excluded region. Even worse, Gaussian statistics are well known to underestimate the tails of “real world” distributions, so that outliers are far more common than naively expected. In many fields, e.g., particle physics, a five sigma limit is being used to claim an actual detection. Although our results are likely affected by galactic contamination effects [43], to remark that this part of the CMB spectrum is most at low multipoles than the CDM one. However, we want to point out that this part of the CMB spectrum is most likely affected by galactic contamination effects [43], and without a more accurate investigation we should not

IV. RESULTS

In this section we discuss different aspects of our results. We start by taking a look at the best-fit models and at the goodness-of-fit of both quintessence and ΛCDM models. Then we show that the introduction of a time-varying equation of state for the dark energy component does not significantly alter the constraints on the basic cosmological parameters. This allows us to discuss constraints on the time evolution of the quintessence equation of state. In Sec. IV D we use large-scale structure data instead of the supernova data to break the geometric degeneracy. We also check if the combination of both data sets improves the constraints. Finally, we discuss limits on toy “phantom energy” models where we allow $w < -1$.

A. The goodness-of-fit

Our global best-fit QCDM model is characterized by the following dark energy parameters: $w_0 = -1.00$, $w_m = -0.13$, $a_1 = 0.48$, and $\Delta = 0.06$, which correspond to a fast transition in the equation of state at redshift of 1. The total $\chi^2$ of this model is 1602.9, while the best-fit ΛCDM model has $\chi^2 = 1605.8$. However, the total number of degrees of freedom is 1514, so that all our fits are rather bad. This is mainly due to the WMAP data (see the discussion in [3]). In Table I we report the corresponding $\chi^2$ values for the CMB and SN data and best-fit values of the standard cosmological parameters for these two models. Notice that the QCDM model provides the best fit to both the CMB and SN data.

It is intriguing that such a model has a time evolving equation of state $w(z)$ similar to that reconstructed from the best-fit to the SN data in [40–42]. In Fig. 2 we plot the temperature anisotropy power spectrum for these two models. It is remarkable how perfectly the two completely different models agree at intermediate $\ell$, demonstrating the power of the WMAP CMB data. At low multipoles the additional freedom of the QCDM models allows a slightly better fit. In fact due to a different distribution of the ISW these QCDM best-fit models have less power at low multipoles than the ΛCDM one. However, we want to remark that this part of the CMB spectrum is most likely affected by galactic contamination effects [43], and without a more accurate investigation we should not

![FIG. 2. CMB power spectrum for the QCDM (red solid line) and ΛCDM (blue dashed line) best-fit models.](image-url)
place too much emphasis on this suppression of power. It is worth noticing that the difference in the best-fit cosmological parameters between QCDM and ΛCDM will lead to different TT power spectra at higher multipoles, \( l > 700 \). This suggest that an accurate detection of the third peak may increase the statistical weight in favor or against the QCDM model.

The fact that the \( \chi^2 \) improves by three through the addition of the three new dark energy parameters, is to be expected. Nevertheless we see that some quintessence models provide a better fit to the data than standard ΛCDM, as opposed to analyses which assume that \( w \) is constant. As we will discuss later, the limits on the time evolution of the dark energy equation of state are still compatible with a number of proposed scalar field scenarios.

Studying the distribution of the \( \chi^2 \) values in the MCMC chains for the ΛCDM models, we find that \( \Delta \chi^2 = 6.4 \) for the models at 1σ (68.3% CL) and \( \Delta \chi^2 = 11.8 \) at 2σ (95.4% CL). In the Gaussian case, this corresponds to about 5.5 independent degrees of freedom, slightly less than the number of cosmological parameters used (A1).

For the quintessence models we find \( \Delta \chi^2 = 9.9 \) for 1σ and \( \Delta \chi^2 = 15.5 \) for 2σ. Assuming Gaussian errors, this would mean that we are dealing with about eight independent degrees of freedom, many less than the six cosmological and four dark energy parameters used in the analysis. We conclude that we are unable to constrain all the additional parameters.

Is the improved \( \chi^2 \) of the best-fit QCDM models a positive evidence for the additional dark energy parameters? The answer to this question requires an estimation of the information criteria associated with the model \(^{[44]}\). In general adding more parameters tends to improve the fit to data, however one should reward those models that can produce the same goodness-of-fit with fewer parameters. This can be achieved through the Akaike information criterion (AIC \(^{[45]}\)) and Bayesian information criterion (BIC \(^{[46]}\)), respectively, defined as

\[
\text{AIC} = -2 \ln L + 2k, \tag{4}
\]

and
\[
\text{BIC} = -2 \ln L + k \ln N, \tag{5}
\]

where \( L \) is the maximum likelihood, \( k \) is the number of parameters of the model and \( N \) is the number of data-points. The ΛCDM models have an AIC of 1617.8, while the QCDM models of 1622.9. Based on this difference of 5 we conclude that four parameter dark energy models are not necessarily favored. The BIC disfavors the new parameters even more strongly. The information criteria therefore suggest that current data provide no positive evidence that the dark energy is anything more complex than a cosmological constant. This is not surprising, but should not be used as a reason to stop searching for ways of detecting evidence of evolution. The rewards from finding such evidence would be huge.

B. Constraints on cosmological parameters

The class of quintessence models could \textit{a priori} contain new, severe degeneracies which change completely the preferred values of the cosmological parameters. If this were the case, then all the standard results of the WMAP analysis \( ^{[3]} \) would only be valid in the context of a ΛCDM model. We have found this not to be the case. The new dark energy parameters are degenerate amongst themselves but do not introduce any new degeneracy with the other cosmological parameters. This can be seen in Fig. 3 where quintessence model results are compared with those ob-

![Fig. 3 (color online). Marginalized likelihoods for the various cosmological parameters in the ΛCDM scenario (blue solid curve) and including the QCDM models (yellow shaded region). Also shown are QCDM models with a prior on the baryon energy density \( \Omega_b h^2 = 0.0216 \pm 0.002 \) (red dashed line). The results agree very well in all cases.](083006-5)
tained for ΛCDM models only. Unless specifically stated, the quoted results have been obtained using a linear parametrization of $a$, and a logarithmic one of $\Delta$ in the MCMC. This maximizes the weight of models with a late rapid transition, other parametrizations lead to an even slightly better agreement between ΛCDM and QCDM.

We notice that all parameters, with the possible exception of the reionization optical depth $\tau$, are well determined in both cases. Also, their values are very similar and cannot be distinguished even at 1 standard deviation. Table II lists the best-fit values of the cosmological parameters for the ΛCDM and the dark energy models. The constraint on $h$ is consistent with the HST measurement [30], while the amount of clustering matter $\Omega_m$ is in agreement with large-scale structure estimates [47,48]. The physical baryon density is consistent with the big bang nucleosynthesis expectations [49]. This provides an important cross-check that all viable models have to pass. The background universe is therefore largely independent of the details of the dark energy.

We find nonetheless some differences, but they can be explained quite easily. First, these are the marginalized likelihoods. The remaining degeneracy in $\Omega_m$, $H_0$, and $w_0$ is therefore translated into a slight shift to lower values in both $\Omega_m$ and $H_0$. The degeneracy between the physical baryon density, $\Omega_bh^2$, and the scalar spectral index, $n_s$, becomes slightly worse (see Fig. 4), leading to somewhat longer tails in their likelihood distributions. This is a consequence of the larger integrated Sachs-Wolfe (ISW) effect produced in time dependent dark energy models with the respect to the ΛCDM case [28]. In fact the ISW boosts power on the large angular scales of the CMB, therefore less power of the primordial fluctuation power spectrum at small wavenumber $k$ is required to match the data. Consequently slightly blue shifted spectral index values are preferred. The same effect is also responsible for the spread of the likelihood distribution of the reionization optical depth through the degeneracy between $n_s$ and $\tau$. For larger values of $n_s$ the excess of power at the low multipoles of the TE spectrum requires larger values of the optical depth (see Fig. 5). Since the reionization suppresses the contribution at high $\ell$ with a factor of $e^{-2\tau}$ a better determination of the CMB peak structure as well as better polarization data will help to break this degeneracy. We hope that the latter will be available shortly, when WMAP releases the two-year data.

Figure 3 shows also the effect of introducing a prior on $\Omega_bh^2$, namely $\Omega_bh^2 = 0.0216 \pm 0.002$. As we can see, the prior only affects the cosmological parameters $\tau$, $n_s$ and $\Omega_bh^2$ and removes some of their high values. None of the dark energy parameters are affected (see

### Table II

Mean and (formal) standard deviations for the cosmological parameters. The ΛCDM values agree with published analyses. The QCDM values are always consistent within 1 standard deviation, showing that quintessence does not significantly impact "precision cosmology."

C. Constraints on the dark energy parameters

As we have seen in the previous section, the additional parameters which describe the dark energy do not introduce any new degeneracies with the standard cosmological parameters. However we expect the dark energy parameter space to have an internal degeneracy. For instance $w_0$ and $w_m$ both act on physical observables as an equation of state parameter. Therefore slowly varying models with $w_m < -0.08$ at $2\sigma$, on the other hand $a_i$ and $\Delta$ remain unconstrained. We refer to [34] for a discussion on breaking such a degeneracy with an estimate of the value of $\sigma_8$ from large-scale structure.

A parametrization in $\log(a_i)$ would place more emphasis on early transitions, so that the effective redshift where $w_m$ is evaluated is moved to higher values. In this case the limits on $w_m$ become even weaker, and we conclude that $w_m$ as a parameter is difficult to interpret. On the other hand, the limits on $w(z)$ as a function of redshift are less dependent of the parametrization of $a_i$, as we derive them at all redshifts separately. We therefore advocate these limits, as plotted in Fig. 7, as a better illustration of the constraints on dark energy models.

These limits, derived with the Markov chain approach, rest solely on the local density of the accepted models. If the assumption of Gaussian errors holds approximately, then we can derive the same limits using the actual likelihood values instead. In this case, and considering a single variable, models with $\Delta \chi^2 > 4$ occur $95.4\%$ of the time. We find that models with $w_0 > -0.25$ have $\Delta \chi^2 > 4$, consistent with the limits from the Markov chain. In order to put limits on the equation of state as a function of
redshift, we proceed as follows: we compute \( w(z) \) for each model and then take either the 95% confidence region over all models in the chain (shaded area in Fig. 7) or compute the highest \( w(z) \) for models with \( \chi^2 < \chi^2_{\text{min}} + 4 \) (dashed line).

The shaded area is a priori the proper marginalized result, representing the 95% limits on \( w(z) \). However it is worth remarking that this constraint may suffer from a potential problem with the choice of the measure that we introduce to integrate the marginalized parameters over (see discussion in Sec. III). On the other hand the dashed line relies only on the goodness-of-fit, and can be interpreted as an exclusion limit. In other words models with a \( w(z) \) that enter the hatched area are a “bad” fit to the data. This does not include any information about how likely these models are, given the variation in the other parameters. Our interpretation of this is as follows: if we want to judge if a single, specific model is ruled out or not, then we should be using the dashed line as an upper limit for \( w(z) \). If we are more interested in what we would expect as the value of \( w(z) \), given our additional knowledge about the other variables, then we should look at the shaded region as providing a limit on the equation of state parameter. As we can see in Fig. 7, models with \( w_m \gtrsim 0 \) at \( z > 1 \) and with a fast transition occurring at \( z \lesssim 1 \) are a bad fit to the data, being beyond the dashed blue line. Physically this is because models where the transition from \( w_m \) to \( w_0 \) occurs at redshifts \( z < 10 \) with \( w_m > -0.1 \) give rise to a non-negligible dark energy contribution at decoupling, which is strongly constrained by CMB data. However, models with \( w_0 < 0.8 \) and \( w_m > -0.1 \) for which the transition occurs at redshift \( z > 10 \) are consistent with the data as their early energy contribution is negligible. As mentioned earlier, the apparent exclusion of these models based on the likelihood for \( w_m \) in Fig. 6 is an artifact of our parametrization of \( a_r \). This can also be seen by noticing that the maximized results (dashed curve) does not fall to zero for \( w_m > 0 \), indicating that there are acceptable models in this part of the parameter space. However these models will be indistinguishable from a pure \( \Lambda \text{CDM} \) scenario and are thus not very interesting when we try to rule out one from the other.

The limits on \( w(z) \) can be reinterpreted as constraints on the evolution of the dark energy density (see Fig. 8). Models with \( \Omega_{\text{DE}}(z) \) above the dashed line are ruled out, thus limiting the amount of dark energy available during matter domination to be \( \Omega_{\text{DE}}(z) < 0.1 \) (see also [50,52]).

These results undoubtedly have an effect for quintessence model building, and we will be investigating this aspect in a future paper. For now though we restrict ourselves to a few general remarks. The limits on \( w(z) \) previously obtained allow us to constrain a large class of quintessence models. For instance the exclusion plot in Fig. 7 suggests that models with a perfect tracking behavior, for which \( w = 0 \) during the matter era up to \( z \lesssim 4 \), and with a late-time fast transition, are disfavoured by the data. As we have seen before, this is because \( \Omega_0 \) must be negligible at early times. This class of models, for some particular choice of the parameters of the scalar field potential, include the two exponential potential [53] and the Albrecht-Skordis model [54]. Of course, if they leave their tracking behavior before then, the constraint is weakened. These models satisfy the constraints only if the slope of the scalar field potential, where the quintessence is initially rolling down, is very steep and then followed by a nearly flat region such that the equation of state \( \approx -1 \) at the present time. On the other hand models with a nonperfect tracking behavior and a slowly varying equation of state with \( w_0 < -0.8 \) are consistent with the data. This is the case of quintessence models with an inverse power law potential [7], supergravity inspired potentials such as the one proposed in [55] or off-tracking quintessence models, such as those studied in [56,57]. Models of late-time transition [58] which show features of our best-fit model can also be consistent with the data.

\[\text{D. Adding large-scale structure}\]

One important question is whether the supernova data contains any severe systematic effects that may strongly bias our results. To test for this possibility, we replace the supernova data by the 2dF galaxy redshift survey power spectrum from Ref. [36]. The bias is added as a new, free parameter. This means that only the form of \( P(k) \) is constrained, not its amplitude. The solid lines in Figs. 9 and 10 show the resulting likelihoods of the cosmological and the dark energy parameters, respectively. Comparing
them to the CMB+SN-Ia results (shaded yellow regions), we find that the results are consistent, but that the supernovae allow us to place stronger constraints on $\Omega_m$, $H_0$, and $w_0$ when combined with the CMB. There is no evidence for any systematic problems in the SN-Ia data set. Additionally, we can use the combination of all three data sets. In [23] we found that the LSS does not add any strong constraints, beyond those found with CMB+SN-Ia data, as long as no constraints on the bias parameter are imposed. As the dashed curve in Figs. 9 and 10 shows, this is still the case, and the bias parameter is strongly correlated with the clustering strength, $\sigma_8$. The constraints on the bias found in [59] do not apply to our analysis, since they were obtained by combining the SDSS 3D matter power spectrum with the WMAP results on $\sigma_8$ which are correct only for $\Lambda$CDM cosmologies.

For standard quintessence models one can thus either use supernovae or large-scale structure data, with the supernova data giving the stronger constraints. The situation changes if additional parameters need to be constrained, e.g., nonzero neutrino masses. In this case it is crucial to have very good clustering data on small scales where the neutrinos impose a distinct signal on $P(k)$.

E. Phantom energy models

Several authors have suggested that dark energy models with a supernegative equation of state, for which $w < -1$, can provide a better fit to the CMB and the SN-Ia data [21,60–63]. On the other hand all these analyses are biased in favor of phantom dark energy models since they use a constant equation of state parameter [64,65]. In this scenario the dark energy violates the weak energy condition (WEC) which leads to a number of problems [66]. For this reason we feel that these models are disfavoured on theoretical grounds. Nevertheless it remains an interesting question whether they are compatible with the current cosmological observations? Constraining time dependent phantom energy models allows us the opportunity to test these models against the observational data without the bias induced by assuming a constant equation of state parameter. However the main problem for this class of models is the existence of tachyon instabilities which lead to an exponential growth of phantom energy perturbations on small scales. In addition our formalism does not allow us to follow the evolution of

FIG. 9 (color online). Constraints on the cosmological parameters when adding the 2dFGRS data to CMB and SN–Ia data (blue dashed line) and when only using CMB+2dFGRS (black solid line), compared to the CMB+SN-Ia case (yellow shaded region).

FIG. 10 (color online). Constraints on the dark energy parameters when adding the 2dFGRS data to CMB and SN–Ia data (blue dashed line) and when only using CMB+2dFGRS (black solid line), compared to the CMB+SN-Ia case (yellow shaded region).
the dark energy perturbations for phantom models which cross the $w = -1$ value (see discussion in Appendix B). On the other hand we can account for the perturbations in models which violate the weak energy condition at all times.

In order to be self-consistent we therefore extend our analysis to two different classes of dark energy models, those which always satisfy/violate the WEC and those which cross the WEC boundary value $w = -1$. The latter are assumed to be homogeneous and consequently our analysis for these class of models accounts only for the effects they produce on the background expansion. Although this is not physical, we are unaware of a unique prescription for handling these cases. We therefore suggest that the reader see this section more as a speculative treatment. It is interesting to note that in these “toy” phantom models, the allowed values of the cosmological parameters do not change very much, in that they lie somewhere between the ΛCDM and the QCDM case (see Fig. 11).

The models which cross $w = -1$ provide a slightly improved best fit. In particular we find a best-fit model with $\chi^2 = 1601$. It has $w_0 = -2.0$ and $w_m = -0.7$, i.e., the equation of state crosses over that of the cosmological constant, $p = -\rho$. This behavior is most likely driven by the supernova data, as we find a similar result if we only use this data set [27]. In Fig. 12 we plot the 1D marginalized likelihoods for the dark energy parameters.

For the standard parametrization of $a_i$ and $\Delta$, the median for $w_0$ is $-1.1$ and for $w_m$ is $-0.8$. The 95% confidence intervals are $-2.7 < w_0 < -0.77$ and $-8.3 < w_m < -0.19$. For the models that do not cross $w = -1$, but always remain either with $w < -1$ or $w \geq -1$, the results give the median for $w_0$ to be $-1.0$ and for $w_m$ to be $-0.97$. The overall best-fit model is the same as for the standard QCDM models, but as the above median values show there are about the same number of accepted models on both sides of the divide.

Thus there is no evidence for any deviation from ΛCDM in this extended framework.

The parameter which does show some change is the clustering amplitude, $\sigma_8$, which lies now in the 95% confidence interval $0.66 < \sigma_8 < 1.24$ as opposed to the dark energy models satisfying the weak energy condition $w \geq -1$ for which $0.53 < \sigma_8 < 1.07$.

The limits on $w(z)$ are shown in Fig. 13. The shaded regions correspond to all models which do not cross $w = -1$. We display the 1D marginalized likelihoods for $w_0$, $w_m$, $a_i$, and $\Delta$ in Figs. 12.
The remaining cosmic parameters are only mildly affected by the new freedom given to dark energy and are similar to their ΛCDM counterparts. On the down side, with regard to the dark energy parameters, the currently available data set means that only the present value of the equation of state $w_0$ is well constrained. We find $w_0 < -0.8$ at 95% confidence level. By studying the behavior of $w(z)$, we conclude that the constraints become weak for any redshifts larger than about unity.

However, there are some clear results that emerge. For example in the large class of Quintessence models that have periods of perfect tracking behavior, i.e., $w = 0$ during the matter dominated era, only those which track for during the period $z \geq 5$ are acceptable. Quintessence models with a very late departure from tracking, or any dark energy models with a late transition from a high value of $w$, are disfavoured as a consequence of the fact that early contributions of dark energy are constrained to be negligible.

We have also found a point of practical importance in the hunt for dark energy dynamics. Since only rapidly varying models at low redshift have a distinct signature as opposed to ΛCDM [28] including such models in ones likelihood analysis is very important, otherwise the results will be biased towards no detection of dynamics. However these rapidly varying models are the most susceptible to numerical errors, which we have found can be as large as 5%. We therefore have used a code specially adapted to handle these “kink” cases, and this is described in Appendix C.

We have also studied toy models for which $w < -1$ is possible. In this case the perturbations are generically unstable, and so we turned them off for any model which enters $w < -1$ at any point. In this case models that have $w$ slightly larger than $-1$ at early times and show a rapid, late transition to a supernegative equation of state, $w \leq -2$, are slightly, but not significantly, preferred. In a slightly more physical model where $w = -1$ cannot be crossed, allowing us to compute the perturbations, we find no preference for these “phantom” models.

Overall, we conclude that dynamical models of dark energy are by no means ruled out and provide a slightly better fit to current data than ΛCDM. The latter is still perfectly acceptable and, given its simplicity, seems in many ways the preferred model at the current time. Whether observations and theoretical prejudice maintain this conclusion over the coming years will have a profound impact on our understanding of fundamental physics.

ACKNOWLEDGMENTS

We are grateful to Michael Doran for testing our models with CMBEASY and for the very useful discussions and suggestions. P.S.C. thank Axel De La Macorra for the interesting discussions and the hospitality at the
APPENDIX A: PARAMETRIZATION OF THE MODELS

A simple way of describing a dark energy component is to consider a constant equation of state \( w \). However such an approach suffers from a number of drawbacks. In fact assuming \( w \) to be constant introduces a bias in the analysis of cosmological distance measurements with the consequence that large negative values of \( w \) are favored if the dark energy is time dependent [64,65]. The effect of this bias has to be carefully taken into account particularly when models of phantom energy [60,66], for which \( w < -1 \), are constrained. A possible way to address this issue is to constrain a time dependent parametrization of \( w(z) \). In fact the time dependence of the dark energy equation of state completely specifies the evolution of the dark energy density through the continuity equation. Several formula have been proposed in the literature [69–71] all with limited applicability. They are typically based on Taylor expansions in some variable (e.g., \( z, \log(1 + z), \) or \( 1 - a \)). However, tracking quintessence models exhibit the important property that before the universe begins to accelerate the dark energy has an equation of state which mimics that of the dominant energy component. Today of course \( w < -1/3 \), so there must be a transition between the value at high redshifts and that at the present time at some critical redshift, \( z_t \), or equivalently scale factor, \( a_t = 1/(1 + z_t) \), with a thickness determined by a parameter \( \Delta \). In fact, this physically motivated parametrization bears a striking resemblance to the \( \text{tanh}(z) \) kink soliton solution in spirit.

To compare various proposals we write it as:

\[
 w(a) = w_0 + (w_m - w_0) \Gamma(a, a_t, \Delta), \tag{A1}
\]

where \( \Gamma \) determines precisely how the transition from \( w = w_m \) to \( w = w_0 \) occurs. Two proposals for \( \Gamma \) have been made in the literature. The original one [17,23] uses \( z \) instead of \( a \):

\[
 \Gamma(z, z_t, \Delta) = \frac{-1}{1 + e^{z - z_t}/\Delta} \tag{A2}
\]

while a different proposal (and the one that we use here) was made in [26], namely:

\[
 \Gamma(a, a_t, \Delta) = \frac{1 + e^{a - a_t}/\Delta}{1 + e^{-(a - a_t)/\Delta}} \times \frac{1 - e^{-(a - 1)/\Delta}}{1 - e^{a/\Delta}}. \tag{A3}
\]

The latter form has the advantage of being more stable numerically (since \( a \) is bounded in the interval \([0, 1]\) while redshifts up to \( z = 10^4 \) must be considered in the first form) and satisfies \( w(a = 1) = w_0 \) whereas the same is only true for sufficiently rapid transitions in Eq. (A2).

Because of this we use the latter form (A3) in this paper. Importantly, this form can also be extended [26] to allow for a different value of \( w \) during radiation domination so that it can represent tracking models faithfully at all redshifts in terms of five physical parameters: the value of the equation of state today \( w_0 \), during the matter era \( w_m \) and during the radiation era \( w_r \), while the time dependence is specified by the value of the scale factor \( a_t \) where the equation of state changes from \( w_m \) to \( w_0 \) and the width of the transition \( \Delta \). Since big bang nucleosynthesis bounds limit the amount of dark energy to be negligible during the radiation dominated era [73] the extra freedom is not particularly important and we further reduce our parameter space by setting \( w_r = w_m \) yielding the transition function (A3).

Written out fully then, the equation of state we use in this paper is Eq. (4) of Ref. [26]:

\[
 w(a) = w_0 + (w_m - w_0) \frac{1 + e^{a - a_t}/\Delta}{1 + e^{-(a - a_t)/\Delta}} \times \frac{1 - e^{-(a - 1)/\Delta}}{1 - e^{a/\Delta}}. \tag{A4}
\]

The dark energy parameters specified by the vector \( W_{DE} = (w_0, w_m, a_t, \Delta) \) with the parametrization given by Eq. (A4) can account for most of the dark energy models proposed in the literature (see [26] for a detailed discussion). For instance, models characterized by a slowly varying equation of state, such as supergravity inspired models [55], correspond to a region of our parameter space for which \( 0 < a_t/\Delta < 1 \), while models with a rapid variation of \( w(a) \), such as the two exponential potential [53] or the Albrecht-Skordis model [54], correspond to \( a_t/\Delta > 1 \). Models with a simple constant equation of state are given by \( w_0 = w_m \). We can account also for the so-called phantom energy models for which \( w_0, w_m < -1 \). The cosmological constant model corresponds to the following cases: \( w_0 = w_m = -1 \) or \( w_0 = -1 \) and \( a_t \leq 0.1 \) with \( a_t/\Delta > 1 \).

APPENDIX B. COSMOLOGICAL EVOLUTION OF SCALAR FIELDS

The cosmological evolution of minimally coupled quintessence field \( Q \) is described by the Klein-Gordon equation,

\[
 Q'' + 2 \frac{a'}{a} Q' + a^2 \frac{dV}{dQ} = 0, \tag{B1}
\]

the prime denotes derivatives with the respect to conformal time, \( V(Q) \) being the scalar field potential and

\[
 083006-12
\]
\[
\left(\frac{a'}{a}\right)^2 = \frac{8\pi G}{3} \left[ \rho_m + \rho_r + \frac{Q^2}{2a^2} + V(Q) \right],
\]  
(B2)

where \(\rho_m\) and \(\rho_r\) are the matter and radiation energy density, respectively. The equation of motion for the quintessence fluctuations at the scale \(k\) in the synchronous gauge is given by

\[
\delta Q'' + 2 \frac{a'}{a} \delta Q' + \left( a^2 \frac{d^2 V}{d Q^2} + k^2 \right) \delta Q = -\frac{1}{2} Q' h',
\]  
(B3)

where \(h\) is the metric perturbation. Instead of specifying the scalar field potential \(V(Q)\) the conservation of the energy momentum tensor allows us to describe a scalar field as a perfect fluid with a time dependent equation of state \(w(a)\). In such a case the dark energy density evolves according to

\[
\rho_{DE}(a) = \frac{3H_0^2}{8\pi G} \Omega_{DE}(a) \exp \left[ -3 \int_a^1 \frac{1 + w(s)}{s} ds \right],
\]  
(B4)

where \(H_0\) is the value of the Hubble parameter and \(\Omega_{DE}\) is the dark energy density. We can describe the perturbations in a dark energy fluid specified by \(w(a)\) using Eq. (B3) with the second derivative of the scalar field potential is written in terms of the time derivatives of the equation of state \(w(a)\) [74],

\[
a^2 \frac{d^2 V}{d Q^2} = -\frac{3}{2} (1 - w) \left[ \frac{a''}{a} - \left( \frac{a'}{a} \right)^2 \frac{7}{2} + \frac{3}{2} w \right] + \frac{1}{1 + w} \times \left[ \frac{w'^2}{4(1 + w)} - \frac{w''}{2} + \frac{w''}{a(3w + 2)} \right].
\]  
(B5)

For models with an equation of state rapidly evolving towards \(w = -1\) the Eq. (B5) is undefined since \(w = -1\) and \(w', w'' = 0\) at the transition to \(-1\). This corresponds to the fact that at the classical level the vacuum state has no perturbations and quantities such as the sound speed are not defined anymore. When such conditions are realized by one of our models in the MCMC chain, we set the dark energy density perturbations to zero by the time at which \(w = -1\). On the other hand Eq. (B5) becomes singular at \(w = -1\) if \(w', w'' \neq 0\), which could be the case for phantom dark energy models with \(w(a)\) crossing the value \(-1\). On the contrary perturbation in a time dependent phantom fluid with \(w < -1\) at all the time can be described in our framework by switching the negative sign in front of the second derivative of the potential in Eq. (B3).

**APPENDIX C: THE BOLTZMANN CODE - KINKFAST 1.0.0**

We have modified the CMBFAST 4.5.1 to implement our parameterization of dark energy (KINKFAST 1.0.0). We have tested the numerical accuracy of our code by comparing the power spectra of different dark energy models with those computed by using CMBEASY [75]. We find a perfect agreement within 1%. On the other hand we notice that the current version of CMBFAST 4.5.1, which implements the dark energy by reading a redshift sampled equation of state, leads to wrong spectra in the case of dark energy models with a rapid evolution in the equation of state (see Fig. 14). The cause of such a discrepancy is that the dark energy density is obtained through a splint integration procedure of the sampled equation of state. We find this method to be of poor accuracy. Without an analytic formula for \(w(z)\), it is more reliable to derive a polynomial fitting function for the sampled equation of state and integrate the corresponding polynomial form with standard numerical recipes [76] integration subroutines such as rombint.
