ABSTRACT
We study the luminosity function and clustering properties of subsamples of local galaxies selected from the Stromlo–APM Survey by the rest-frame equivalent widths of their Hα and [O II] emission lines. The b1 luminosity function of star-forming galaxies has a significantly steeper faint-end slope than that for quiescent galaxies: the majority of sub-L* galaxies are currently undergoing significant star formation. Emission-line galaxies are less strongly clustered, both amongst themselves and with the general galaxy population, than are quiescent galaxies. Thus as well as being less luminous, star-forming galaxies also inhabit lower density regions of the Universe than quiescent galaxies.

Key words: surveys – galaxies: clusters: general – galaxies: luminosity function, mass function – cosmology: observations.

1 INTRODUCTION

Important clues to the physics of galaxy formation and evolution may be obtained by studying the global properties, such as the luminosity function and correlation function, of quiescent versus star-forming galaxies. The most reliable tracer of the formation rate of massive, hot stars is the flux of the Hα emission line, directly related to the stellar UV (< 912 Å) photoionizing flux (Kennicutt 1983). This line is frequently redshifted out of the observed spectral window, and so most deep galaxy surveys have instead used the [O II] 3727-Å line as a measure of star formation rate (Kennicutt 1992).

The luminosity function of galaxies subdivided by the presence or absence of the [O II] emission line has been calculated in the local Universe for the Las Campanas Redshift Survey (LCRS, Lin et al. 1996a) and for the European Southern Observatory (ESO) Slice Project (ESP, Zucca et al. 1997). In both surveys it was found that the faint end of the galaxy luminosity function is dominated by [O II] emitters, in other words that presently star-forming galaxies tend to be less luminous than quiescent galaxies in both the b1 (ESP) and Gunn-r (LCRS) bands. These results from [O II]-selected samples are consistent with the recent luminosity function estimates from local samples of galaxies selected by morphological (e.g. Marzke et al. 1998) and spectral (e.g. Bromley et al. 1998; Folkes et al. 1999) type: early-type (elliptical and lenticular) galaxies tend to be luminous, and late-type (spiral and irregular) galaxies faint.

It is by now also well known (e.g. Davis & Geller 1976; Giovanelli, Haynes & Chincarini 1986; Iovino et al. 1993; Loveday et al. 1995) that galaxies of early morphological type cluster together on small scales more strongly than do late-type galaxies. Since emission-line galaxies (ELGs) tend to be of late Hubble type, we would expect ELGs to be more weakly clustered than non-ELGs, and indeed this has been observed by numerous authors (e.g. Iovino, Melnick & Shaver 1988; Salzer 1989; Rosenberg, Salzer & Moody 1994; Lin et al. 1996b).

In this paper we study the luminosity function and clustering for subsamples of the Stromlo–APM Survey (Loveday et al. 1996) selected by Hα and [O II] emission-line equivalent widths. The Stromlo–APM Survey is ideal for quantifying the statistical properties of emission-line versus quiescent galaxies in the local Universe since it contains a representative sample of different galaxy types and covers a large volume V ≈ 1.38 × 10³ h⁻³ Mpc³. Since the red wavelength coverage of Stromlo–APM spectra extends from 6300 to 7600 Å we are able to detect the Hα (6562.82 Å) line, when present, to a redshift z ≲ 0.16, i.e. beyond the maximum distance reached by the survey. Thus for the first time we are able to classify a large, representative sample of galaxies by the primary tracer of massive star formation, i.e. the equivalent width of the Hα emission line. Measurement of the spectral properties of Stromlo–APM galaxies is discussed by Tresse et al. (1999), hereafter referred to as Paper I. The subsamples selected by their emission-line properties are described in...
Section 2. The luminosity functions of the different samples are compared in Section 3 and in Section 4 we present clustering measurements. We summarize our results in Section 5. Throughout, we assume a Hubble constant of $H_0 = 100h\, \text{km s}^{-1}\, \text{Mpc}^{-1}$ with $h = 1$ and a deceleration parameter $q_0 = 0.5$. The exact cosmology assumed has little effect at redshifts $z \lesssim 0.15$.

### 2 GALAXY SAMPLES

Our sample of galaxies is taken from the Stromlo–APM redshift survey which covers $4300\,\text{deg}^2$ of the south galactic cap and consists of 1797 galaxies brighter than $b_J = 17.15$ mag. The galaxies all have redshifts $z < 0.145$, and the mean is $\langle z \rangle = 0.051$. A detailed description of the spectroscopic observations and the redshift catalogue is published by Loveday et al. (1996).

Of the 1797 galaxies originally published in the redshift survey, 82 have $b_J < 15$. These bright galaxies are excluded from our analysis since they tend to be saturated on the Schmidt plates and hence have unreliable magnitudes. Of the remaining 1715 galaxies, 26 have a redshift taken from the literature, and for seven we could not retrieve the spectra because they were not observed with the dual-beam spectrograph (DBS) of the Australian National University (ANU) 2.3-m telescope at Siding Spring. Also excluded were six blueshifted spectra, three with $cz < 1000\, \text{km s}^{-1}$, and two with too-low signal-to-noise ratio.

The remaining 1671 spectra were flux-calibrated and had their spectral properties measured as described in Paper I. Flux calibration of our spectra is accurate to $\pm 10$–20 per cent, and so in the present paper we have restricted our analysis to galaxy samples selected by the equivalent widths (EWs) of their Hα and [O II] emission lines, which are insensitive to flux calibration errors. Note that since the resolution of our spectra has FWHM = 5 Å, the Hα line can always be deblended from the [N II] doublet.

Of the 1671 measured galaxies, 11 were not part of our core statistical sample, either because they had an uncertain redshift or happened to lie in a part of the sky masked by ‘holes’ around bright stars, etc. Of the remaining 1660 galaxies, 82 could not have EW (Hα) measured as their redshift places the Hα line in a small gap in the red part of the spectrum from 7000–7020 Å (Loveday et al. 1996). For an additional 57 spectra, Hα was seen in emission but could not be measured because of contamination by a sky line, or some other problem with the spectrum; [O II] lines could not be measured for similar reasons for five spectra. Note that lack of EW measurement, while correlated with redshift, is uncorrelated with galaxy morphology, and so we can reliably correct for missing EW measurements. We are thus left with a sample of 1521 galaxies which could be analysed by EW (Hα), and 1655 which could be analysed by EW ([O II]). Histograms of log EW (Hα) and log EW ([O II]) are plotted in Figs 1 and 2 respectively.

We select galaxy subsamples using measured equivalent widths of the Hα and [O II] emission lines. The Hα line is the best tracer of massive star formation (Kennicutt 1983), but we also select samples using the equivalent width of the [O II] line, as this line allows us to compare with other surveys in which Hα is not always within the wavelength range measured. The Hα line is detected with EW $\geq 2$ Å in 61 per cent of galaxies. Of these

---

**Figure 1.** Histogram of log EW (Hα) for all galaxies and for morphologically selected subsamples as labelled. Note that galaxies with no detected Hα are not shown here. The median EW (Hα), including non-detections, is given for each sample after the morphological type.

**Figure 2.** Histogram of log EW ([O II]) for all galaxies and for morphologically selected subsamples as labelled. Note that galaxies with no detected [O II] are not shown here. The median EW ([O II]), including non-detections, is given for each sample after the morphological type.
emission-line galaxies, half have $\text{EW}(\text{H}\alpha) > 15\,\AA$. Thus we form three subsamples of comparable size by dividing the sample at $\text{EW}(\text{H}\alpha)$ of 2 and 15\,\AA. In the case of the $[\text{O}\,\text{iii}]$ line, 60 per cent of galaxies have $\text{EW} \geq 2\,\AA$, and of these half have $\text{EW} ([\text{O}\,\text{iii}]) \geq 9.6\,\AA$. The galaxy samples selected by $\text{H}\alpha$ and $[\text{O}\,\text{iii}]$ equivalent widths are defined in Table 1.

Most galaxies in the Stromlo–APM Survey have had a morphological type (elliptical, lenticular, spiral or irregular) assigned by visual inspection of the galaxy image (Loveday 1996; Loveday et al. 1996). In Table 1 we give the numbers of galaxies of each morphological type in each spectroscopically selected subsample. In Figs 1 and 2 we also plot the distribution of equivalent widths for these morphologically-selected subsamples. The sample labelled ‘Unk’ (unknown) consists of galaxies to which no morphological classification was assigned. We see that early-type galaxies dominate when $\text{H}\alpha$ or $[\text{O}\,\text{iii}]$ emission is not detected and are underrepresented when emission lines are detected. Conversely, the number of irregular galaxies increases significantly in the spectroscopic samples which show strongest star formation. Strong star formation is known to disrupt the regularity in the shape of a galaxy. In the deeper Universe, the apparent increase in the number of irregulars is also related to strong star formation (Brinchmann et al. 1998). Thus, as expected, we find a good correlation between morphological types and emission line equivalent widths. Since they can be measured objectively, spectroscopic properties of galaxies are a more reliable discriminator than visually assigned morphological types. Moreover, a significant fraction of Stromlo–APM galaxies have no morphological type assigned (the column marked ‘Unk’ in Table 1). The low median $\text{EW}(\text{H}\alpha)$ and $\text{EW} ([\text{O}\,\text{iii}])$ for these unclassified galaxies compared with the total sample suggests that many are in fact of early morphological type. The spectral classification described in this section allows these galaxies to be assigned to their appropriate class in a quantitative way.

3 THE GALAXY LUMINOSITY FUNCTION

We estimate the $b_1$ luminosity function (LF) for each galaxy subsample using maximum-likelihood, density-independent methods, so that our results are unbiased by galaxy clustering. We use the Sandage, Tammann & Yahil (1979) parametric maximum-likelihood estimator to fit a Schechter (1976) function,

$$
\phi(L)\,dL = \phi^*(\frac{L}{L^*})^\alpha \exp\left(-\frac{L}{L^*}\right)\,dL.
$$

We correct for random errors in our magnitudes by convolving this luminosity function with a Gaussian with zero mean and rms $\sigma_m = 0.30$ (see Loveday et al. 1992, hereafter L92, for details). We also perform a non-parametric fit to each luminosity function using the stepwise maximum-likelihood estimator of Efstathiou, Ellis & Peterson (1988). This estimator calculates $\phi(L)$ in a series of evenly-spaced magnitude bins and provides a reliable error estimate for each bin by inverting the information matrix. $K$-corrections are applied to each galaxy according to its morphological classification as $E/S0$: 4.14\,\sigma, $S$p$: 2.25\,\sigma, Irr: 1.59\,\sigma, Unk: 2.90\,\sigma.

Before calculating the LF for each spectroscopic subsample defined in Table 1, we first checked that the galaxies omitted from this analysis, i.e. those galaxies for which the $\text{H}\alpha$ or $[\text{O}\,\text{iii}]$ emission lines could not be measured, did not bias the LF measurement relative to the full Stromlo–APM Survey. The LF estimates, using all galaxies except the 194 with no $\text{H}\alpha$ measurement available and all galaxies except the 60 with no $[\text{O}\,\text{iii}]$ measurement, were indeed both consistent with the full sample.

Our estimates of the luminosity function for the $\text{EW}(\text{H}\alpha)$ selected samples are shown in Fig. 3. The inset to this figure shows the likelihood contours for the best-fitting Schechter parameters $\alpha$ and $M^*$. The Schechter parameters and their 1\,\sigma errors (from the bounding box of the 1\,\sigma error contours) are also listed in Table 2. Note that the estimates of $\alpha$ and $M^*$ are strongly correlated and so the errors quoted for $\alpha$ and $M^*$ in the table are conservatively large. We see a trend of faintening $M^*$ and steepening $\alpha$ as $\text{EW}(\text{H}\alpha)$ increases. There is a significantly greater contrast between the H-high and H-mid samples than between the H-mid and H-low samples, despite the rather similar distribution of morphological types in the H-high and H-mid samples as compared with the H-low sample. This suggests that either there is not a simple one-to-one correlation between optical morphology and $\text{EW}(\text{H}\alpha)$, or that the larger fraction of Irr galaxies in the H-high sample are contributing to the steep faint-end slope for this sample.

Luminosity function estimates of the EW ($[\text{O}\,\text{iii}]$) selected samples and errors in the best-fitting Schechter parameters are shown in Fig. 4. The 1\,\sigma error contours for the O-low and O-mid samples overlap and the O-high sample does not show a fainter $M^*$ than non-emission line galaxies. However, the LF for the O-high sample does have a significantly steeper faint-end slope than that for galaxies with only weak or moderate $[\text{O}\,\text{iii}]$ emission.

The fact that we see a systematic dimming of $M^*$ with emission-line EW for the $\text{H}\alpha$-selected sample but not for the $[\text{O}\,\text{iii}]$-selected sample is probably a result of the fact that $\text{EW}(\text{H}\alpha)$ is a measure of the fraction of ionizing photons from OB stars over the flux from the old stellar population emitted in the rest-frame R band which forms the continuum at $\text{H}\alpha$, while $\text{EW} ([\text{O}\,\text{iii}])$ is normalized by the flux from relatively young stars (mainly type A). Thus $\text{EW}(\text{H}\alpha)$ is more sensitive to the current star formation rate and hence blue luminosity enhancement than is $\text{EW} ([\text{O}\,\text{iii}])$.

Note that the LF estimate for late-type galaxies presented by L92 does not have such a steep faint-end slope as we find here for strong emission-line galaxies. In L92 we combined galaxies classified as spiral or irregular as ‘late type’, and so not all of them have strong emission lines. The faint-end slope for early-type galaxies (L92) was much shallower than that measured here for galaxies with no emission lines. At least part of this difference is the result of a bias in the morphological type-dependent LFs of L92, because of the tendency of unclassified galaxies in the Stromlo–APM Survey to be of low luminosity (Marzke et al.)

\( \alpha \) is the faint-end slope and \( M^* \) the characteristic \( b_j \)-magnitude of the best-fitting Schechter function. \( \dot{n} \) is the space density of galaxies in the range \( -22 < M < -15 \) and \( \phi^* \) is the normalization of the Schechter luminosity function, both in units of \( 10^{-3} h^3 \text{Mpc}^3 \). \( \rho_L \) is the luminosity density integrated over the same magnitude range, in units of \( 10^7 L_\odot h^3 \text{Mpc}^{-3} \).
The normalization $\phi^*$ of the fitted Schechter functions was estimated using a minimum variance estimate of the space density $n$ of galaxies in each sample (Davis & Huchra 1982; L92). We corrected our estimates of $n$, $\phi^*$ and luminosity density $\rho_l$ to allow for those galaxies excluded from each subsample. First, all subsamples were scaled by the factor 1715/1660 to account for the 55 galaxies with no EW information available. Secondly, all Hα selected subsamples were scaled by 1660/1578 to account for the 82 galaxies whose Hα line, if present, would have fallen in the ‘red gap’ (Section 2). Samples H-mid and H-high were scaled by an additional factor 1578/1521 to allow for the 57 galaxies in which Hα was seen, but could not be measured. Finally, samples O-mid and O-high were scaled by 1660/1655 to allow for the five galaxies in which [O ii] was seen but not measured. Our final estimates of $n$, $\phi^*$ and $\rho_l$ are given in Table 2. The uncertainty in mean density arising from ‘cosmic variance’ (L92, equation 7) is $\approx 6$ per cent for each sample. However, the errors in these quantities are dominated by the uncertainty in the shape of the LF, particularly by the value of the estimated characteristic magnitude $M^*$.

Using both Hα and [O ii] equivalent widths as indicators of star formation activity, we find that galaxies currently undergoing significant bursts of star formation dominate the faint end of the luminosity function, whereas more quiescent galaxies dominate at the bright end. This is in agreement with the results of Lin et al. (1996a) and Zucca et al. (1997), but in disagreement with Salzer (1989), who finds no significant difference in the LF shapes of star-forming and quiescent galaxies. As pointed out by Schade & Ferguson (1994), Salzer’s sample is biased against weak-lined star-forming and quiescent galaxies. As pointed out by Schade & Ferguson (1994), Salzer’s sample is biased against weak-lined ELGs at low-luminosity, and their re-analysis of his data correcting for this selection effect does find a steep faint-end slope for the LF of star-forming galaxies.

The characteristic magnitude $M^*$ for the O-high sample is about 0.5 mag brighter than that for the H-high sample. This is probably the result of a combination of several factors: (1) a large [O ii] EW can come from a small [O ii] flux and a very red continuum (i.e. a small star formation rate and an old stellar population); (2) the correlation between estimated values of faint-end slope $\alpha$ and characteristic magnitude $M^*$ means that the steeper $\alpha$ of the O-high sample will push the estimated $M^*$ to brighter magnitudes; (3) the errors on $M^*$ are large ($\geq 0.3$ mag), and so the H-high and O-high $M^*$ estimates disagree only at the 1–2σ level.

4 GALAXY CLUSTERING

In this section we measure the clustering properties of the galaxy subsamples. We measure the auto-correlation function of each sample in redshift space, and the cross-correlation function of each galaxy sample with all galaxy types in real space. For both estimates, we first verified that the 194 galaxies missing EW (Hα) measurements and the 60 galaxies missing EW ([O ii]) did not bias the measured clustering relative to the complete sample. Those galaxies excluded because the Hα value fell in the ‘red gap’ lie at redshifts $z \approx 0.06$–0.07. Nevertheless, omitting these galaxies did not significantly affect the measured clustering in real or redshift space.

4.1 Redshift space correlation function

We correct for boundary conditions and the survey selection function by populating the survey volume with a catalogue of ~18 000 random points, the radial density of which matches that expected for each subsample. The number–distance distributions for the six galaxy subsamples analysed here are shown in Fig. 5. These plots also show the expected distributions inferred from the luminosity functions calculated in the previous section. We see that given the tendency for non-ELGs to be luminous and for ELGs to be faint, the ELGs are slightly overdense at large distances ($x \approx 200 h^{-1}$ Mpc) whereas there is an underdensity of non-ELGs at similar distances. This observation is reflected by the increasing $\langle V/V_{\text{max}} \rangle$ with EW (Hα) seen in Table 2, and is probably a result of evolution in emission line strength with redshift (e.g. Broadhurst, Ellis & Glazebrook 1992), occurring at redshifts as low as $z \approx 0.15$. It is unlikely to be a result of the changing projected size of the spectrograph slit at different redshifts as we demonstrated in Paper I. We checked that these discrepancies between observed and expected $N(z)$ distributions did not bias our estimates of $\xi(s)$ by also generating a random distribution according to a fourth-order polynomial fit to the observed radial density of each subsample. Clustering estimates using this random distribution gave results consistent with a random distribution generated according to the predicted radial density.

The auto-correlation function of each sample in redshift space is measured using the estimator

\[ 1 + \xi(s) = \frac{w_{gg}(s)w_{rr}(s)}{w_{gr}(s)^2} \]  

(Hamilton 1993). Here $w_{gg}(s)$, $w_{gr}(s)$ and $w_{rr}(s)$ are the summed

\[ w_{gg}(s) = \frac{1}{N_g n_g} \sum_{i,j} \delta_i \delta_j \delta(s - \tau_{ij}), \quad w_{gr}(s) = \frac{1}{N_g n_r} \sum_{i,j} \delta_i \delta_j \delta(s - \tau_{ij}), \quad w_{rr}(s) = \frac{1}{N_r^2} \sum_{i,j} \delta_i \delta_j \delta(s - \tau_{ij}), \quad w_{gr}(s) = \frac{1}{N_g n_r} \sum_{i,j} \delta_i \delta_j \delta(s - \tau_{ij}) \]
Figure 6. Estimates of the redshift space correlation function for the galaxy samples given in Table 1. Error bars show the rms variance from dividing the survey into four distinct zones. The dashed line shows the best-fitting power-law over the range 1.5–30\,h^{-1}\,Mpc with the index held fixed at $\gamma_s = 1.47$. The dotted line shows $\hat{\xi}(s)$ estimated from the full Stromlo–APM sample (Loveday et al. 1995).

$s_0$ is the correlation length measured in redshift space over the range 1.5–30\,h^{-1}\,Mpc with the power-law index held fixed at $\gamma_s = 1.47$. $\gamma_s$ and $\hat{r}_0$ are the real space power-law parameters over 0.2–20\,h^{-1}\,Mpc determined from cross-correlation with the 2d APM survey (Section 4.2).

4.2 Real space correlation function

The estimate of $\xi(s)$ described above is affected by redshift space distortions. On small scales, random, thermal motions tend to decrease galaxy clustering, whereas on large scales, galaxy streaming motions tend to enhance $\xi(s)$. In order to avoid the

\(\gamma_s\) and correlation length $s_0$ are strongly correlated, we determined the best fit $s_0$ to each subsample, keeping the power-law index fixed at $\gamma_s = 1.47$. The results of these fits are shown by the dashed lines in Fig. 6 and the best-fitting values of $s_0$ with 1σ uncertainties (determined from fitting to each zone separately) are shown in Table 3.

We see that the correlation length $s_0$ becomes significantly smaller in more actively star-forming galaxies, as traced by both EW (Hα) and EW ([O\,III]). This result is in agreement with the power-spectrum analysis of the Las Campanas Redshift Survey by Lin et al. (1996b) who find that the clustering amplitude of ELGs is only about 70 per cent that of the full LCRS sample. These results are also consistent with those of Rosenberg et al. (1994), Iovino et al. 1988 and Salzer (1989), all of whom find that ELGs are less strongly clustered than quiescent galaxies. Galaxies with no detected Hα (H-low) or [O\,III] (O-low) emission have a correlation length about twice that of ELG galaxies (H-high and O-high samples). This is larger than the difference in clustering amplitude determined by Lin et al. (1996b) from the LCRS, presumably because we have subdivided galaxies into three EW bins compared to their two EW bins.
effects of galaxy peculiar velocities, we have calculated the projected cross-correlation function $\xi(r)$ of each galaxy subsample with all galaxies in the APM survey to a magnitude limit of $b_J = 17.15$. We then invert this projected correlation function to obtain the real space cross-correlation function $\xi(r)$ of each subsample with the full galaxy sample. This method of estimating $\xi(r)$ is described by Saunders, Rowan-Robinson & Lawrence (1992) and by Loveday et al. (1995).

The large number of galaxy pairs used by this estimator allows us to fit a power-law to the measured cross-correlation function over the range of separations $0.2-20 h^{-1}$ Mpc and to fit both the power-law index $\gamma$ and the correlation length $r_0$. Our estimates of $\xi(r)$ are plotted in Fig. 7 and our best-fitting power-laws are tabulated in Table 3. As in redshift space, we see that strong emission-line galaxies are more weakly clustered than their quiescent counterparts by a factor of about two.

The real space clustering measured for non-ELGs is very close to that measured for early-type (E + SO) galaxies, and the clustering of late-type (Sp + Irr) galaxies lies between that of the moderate and high EW galaxies (cf. Loveday et al. 1995). Given the strong correlation between morphological type and presence of emission lines (Table 1), this result is not unexpected. The power-law slopes are consistent ($\gamma = 1.8 \pm 0.1$) between the H-low, H-high, O-low and O-high samples. For the moderate EW galaxies (H-mid and O-mid samples) we find shallower slopes ($\gamma = 1.6 \pm 0.1$). This is only a marginally significant ($1-2\sigma$) effect, but may indicate a deficit of moderately star-forming galaxies principally in the cores of high-density regions, whereas strongly star-forming galaxies appear more generally to avoid overdense regions.

5 CONCLUSIONS

We have presented the first analysis of the luminosity function and spatial clustering for representative and well-defined local samples of galaxies selected by EW ([Hα]), the most direct tracer of star formation. We have also selected galaxies by EW ([O III]), and find broadly consistent results between the two tracers of star formation, which is expected from their close relation (Kennicutt 1992; Paper I). The observed trend for $M^*$ to flatten systematically with increasing EW (Hα), contrasted with the roughly constant $M^*$ with varying EW ([O III]), is probably a result of EW (Hα) being a more reliable indicator of star formation rate than EW ([O III]).

Star-forming galaxies are likely to be significantly fainter than their quiescent counterparts. The faint-end ($M \geq M^*$) of the luminosity function is dominated by ELGs and thus the majority of local dwarf galaxies are currently undergoing star formation.

Star-forming galaxies are more weakly clustered, both amongst themselves, and with the general galaxy population, than quiescent galaxies. This weaker clustering is observable on scales from $0.1-10 h^{-1}$ Mpc. We thus confirm that star-forming galaxies are preferentially found today in low-density environments.

A possible explanation for these observations is that luminous galaxies in high-density regions have already formed all their stars, while less luminous galaxies in low-density regions are still undergoing star formation. It is not clear what might be triggering the star formation in these galaxies today. While interactions certainly enhance the rate of star formation in some disc galaxies, interactions with luminous companions can only account for a small fraction of the total star formation in disc galaxies today (Kennicutt et al. 1987). Telles & Maddox (1999) have investigated the environments of HII galaxies by cross-correlating a sample of HII galaxies with APM galaxies as faint as $b_J = 20.5$. They find no excess of companions with HII mass $\geq 10^6 M_\odot$ near HII galaxies, thus arguing that star formation in most HII galaxies is unlikely to be induced by even a low-mass companion.

Our results are entirely consistent with the hierarchical picture of galaxy formation. In this picture, today's luminous spheroidal galaxies formed from past mergers of galactic sub-units in high density regions, and produced all of their stars in a merger-induced burst, or series of bursts, over a relatively short timescale. The majority of present-day dwarf, star-forming galaxies in lower density regions may correspond to unmerged systems formed at lower peaks in the primordial density field (e.g. Bardeen et al. 1986) and in which star formation is still taking place. Of course, the full picture of galaxy formation is likely to be significantly more complicated than this simple sketch, and numerous physical effects such as depletion of star-forming material and other feedback mechanisms are likely to play an important role.

ACKNOWLEDGMENTS

We thank George Efstathiou and Bruce Peterson for their contributions to the Stromlo–APM Survey.
