Measurements of spin correlation in top-antitop quark events from proton-proton collisions at $\sqrt{s} = 7$ TeV using the ATLAS detector

G. Aad et al.*
(ATLAS Collaboration)
(Received 16 July 2014; published 24 December 2014)

Measurements of spin correlation in top quark pair production are presented using data collected with the ATLAS detector at the LHC with proton-proton collisions at a center-of-mass energy of 7 TeV, corresponding to an integrated luminosity of 4.6 fb$^{-1}$. Events are selected in final states with two charged leptons and at least two jets and in final states with one charged lepton and at least four jets. Four different observables sensitive to different properties of the top quark pair production mechanism are used to extract the correlation between the top and antitop quark spins. Some of these observables are measured for the first time. The measurements are in good agreement with the Standard Model prediction at next-to-leading-order accuracy.

I. INTRODUCTION

The top quark is the heaviest known elementary particle. Besides the high mass, it has the shortest lifetime of any quark, determined to be $(3.29^{+0.90}_{-0.63}) \times 10^{-25}$ s [1], which is shorter than the time scale for hadronization [2]. This implies that top quarks can be studied as bare quarks, i.e. quarks before hadronization, and the spin information of the top quark can be deduced from the angular distributions of its decay products.

In the Standard Model (SM) of particle physics, top quarks are produced at hadron colliders in pairs ($t\bar{t}$), predominantly via strong interactions, or singly via the electroweak interactions. At the Large Hadron Collider (LHC), which collided protons ($pp$) at a center-of-mass energy of 7 TeV in 2011, top quarks were mainly produced in pairs via gluon fusion. In the SM, $t\bar{t}$ pairs are produced essentially unpolarized at hadron colliders [3], as has been tested in recent measurements by the D0 Collaboration [4] and the ATLAS and CMS Collaborations [5,6]. Nonetheless, the correlation of the spin orientation of the top quark and the top antiquark can be studied, and is predicted to be nonzero [3,7–24].

New physics models beyond the SM (BSM) can alter the spin correlation of the top quark and top antiquark by modifying the production mechanism of the $t\bar{t}$ pair. Also, they can modify the $t\bar{t}$ decay by which the spin information is accessed. The first scenario occurs, for example, in BSM models where a $t\bar{t}$ pair is produced via a high-mass $Z'$ boson [25,26] or via a heavy Higgs boson that decays into $t\bar{t}$ [27]. The second scenario occurs, for example, in supersymmetric models if a top quark decays into a spin zero particle like a charged Higgs boson, which then decays into a lepton and a neutrino [28,29]. Thus measuring the spin correlation in $t\bar{t}$ events can simultaneously probe top production and (indirectly) decay for potential effects due to new physics.

The measurements of the spin correlation between the top quark and the top antiquark presented in this paper rely on angular distributions of the top quark and top antiquark decay products. The charged leptons and the $d$-type quarks from the $W$ boson decays are the most sensitive spin analyzers, and the $b$ quark from top quark decay contains some information about the top quark polarization, too. Observables in the laboratory frame and in different top quark quantization bases are explored. These variables are used to measure the coefficient $f_{SM}$, which is related to the number of events where the $t$ and $\bar{t}$ spins are correlated as predicted by the SM, assuming that $t\bar{t}$ production consists of events with spin correlation as in the SM or without spin correlation. The measured value of $f_{SM}$ is translated into the spin correlation strength $A$, which is a measure for the number of events where the top quark and top antiquark spins are parallel minus the number of events where they are antiparallel with respect to a spin quantization axis, divided by the total number of events.

The spin correlation in $t\bar{t}$ events has been studied previously at the Tevatron and the LHC. The CDF and D0 Collaborations have performed a measurement of $A$ by exploring the angular correlations of the charged leptons [30,31]. The D0 Collaboration has exploited a matrix element based approach [32] and reported the first evidence for nonvanishing $t\bar{t}$ spin correlation [33,34]. These measurements are limited by statistical uncertainties and are in good agreement with the SM prediction. Using the difference in azimuthal angles of the two leptons from the decays of the $W$ bosons emerging from top quarks in the laboratory frame, $\Delta \phi$, the ATLAS Collaboration reported the first observation of nonvanishing $t\bar{t}$ spin correlation using

2.1 fb$^{-1}$ of LHC data, taken at 7 TeV collision energy \cite{35}. The CMS Collaboration also measured spin correlations in dileptonic final states at 7 TeV using angular correlations of the two charged leptons and the $\Delta \phi$ observable with 5.0 fb$^{-1}$ of data \cite{6}, showing good agreement with the SM prediction.

In this paper, measurements of $\vec{n}$ spin correlation using the full 7 TeV data sample of 4.6 fb$^{-1}$ collected by the ATLAS Collaboration are presented. Using events with one or two isolated leptons in the final state, spin correlations are measured using $\Delta \phi$ between the lepton and one of the final-state jets or between the two leptons, respectively. Additional measurements are performed in the final state with two leptons, using observables that are sensitive to different types of sources of new physics in $\vec{n}$ production. In particular, angular correlations between the charged leptons from top quark decays in two different spin quantization bases and a ratio of matrix elements in the dileptonic channel are also measured.

II. THE ATLAS DETECTOR

The ATLAS experiment \cite{36} is a multipurpose particle physics detector. Its cylindrical geometry provides a solid angle coverage close to $4\pi$.$^1$

Closest to the interaction point is the inner detector, which covers a pseudorapidity range $|\eta| < 2.5$. It consists of multiple layers of silicon pixel and microstrip detectors and a straw-tube transition radiation tracker (TRT). Around the inner detector, a superconducting solenoid provides a 2 T axial magnetic field. The solenoid is surrounded by high-granularity lead/liquid-argon electromagnetic (EM) calorimeters and a steel/scintillator-tile hadronic calorimeter in the central region. In the forward region, end-cap liquid-argon calorimeters have either copper or tungsten absorbers.

The muon spectrometer is the outermost part of the detector. It consists of several layers of trigger and tracking chambers organized in three stations. A toroidal magnet system produces an azimuthal magnetic field to enable an independent measurement of the muon track momenta.

A three-level trigger system \cite{37} is used for the ATLAS experiment. The first level is purely hardware-based and is followed by two software-based trigger levels.

III. OBJECT RECONSTRUCTION

In the SM, a top quark predominantly decays into a $W$ boson and a $b$ quark. For this analysis $\vec{n}$ candidate events in two final states are selected. In the dilepton final state, both $W$ bosons emerging from top and antitop quarks decay leptonically into $e\nu_e$, $\mu\nu_\mu$, or $\tau\nu_\tau$, \textsuperscript{2}with the $\tau$ lepton decaying into an electron or a muon and the respective neutrinos. In the single-lepton channel, one $W$ boson from the top or antitop quark decays leptonically, while the other $W$ boson decays into a quark-antiquark pair.

Events are required to satisfy a single-electron or single-muon trigger with a minimum lepton transverse momentum ($p_T$) requirement that varies with the lepton flavor and the data-taking period to cope with the increasing instantaneous luminosity. During the 2011 data-taking period the average number of simultaneous $pp$ interactions per beam crossing (pileup) at the beginning of a fill of the LHC increased from 6 to 17. The primary hard-scatter event vertex is defined as the reconstructed vertex with at least five associated tracks and the highest sum of the squared $p_T$ values of the associated tracks with $p_T > 0.4$ GeV.

Electron candidates \cite{38} are reconstructed from energy deposits (clusters) in the electromagnetic calorimeter that are associated with reconstructed tracks in the inner detector. They are required to have a transverse energy, $E_T$, greater than 25 GeV and $|\eta_{\text{cluster}}| < 2.47$, excluding the transition region $1.37 < |\eta_{\text{cluster}}| < 1.52$ between sections of the electromagnetic calorimeters. The electron identification relies on a cut-based selection using calorimeter, tracking, and combined variables such as those describing shower shapes in the EM calorimeter’s middle layer, track quality requirements and track-cluster matching, particle identification using the TRT, and discrimination against photon conversions via a hit requirement in the inner pixel detector layer and information about reconstructed conversion vertices. In addition, to reduce the background from nonprompt electrons, i.e. from decays of hadrons (including heavy flavor) produced in jets, electron candidates are required to be isolated from other activity in the calorimeter and in the tracking system. An $\eta$-dependent 90% efficient cut based on the transverse energy sum of cells around the direction of each candidate is made for a cone of size $\Delta R = \sqrt{(\Delta \phi)^2 + (\Delta \eta)^2} = 0.2$, after excluding cells associated with the electron cluster itself. A further 90% efficient isolation cut is made on the sum of track $p_T$ in a cone of radius $\Delta R = 0.3$ around the electron track. The longitudinal impact parameter of the electron track with respect to the event primary vertex, $\delta z_0$, is required to be less than 2 mm.

Muon candidates are reconstructed from track segments in various layers of the muon spectrometer and are matched with tracks found in the inner detector. The final muon candidates are refitted using the complete track information from both detector systems, and are required to have $p_T > 20$ GeV and $|\eta| < 2.5$. Each muon candidate is required to be isolated from jets by a distance $\Delta R > 0.4$. In addition, we use the notation $e\nu_e$ for both $e^+\nu_e$ and $e^-\bar{\nu}_e$. The same applies to $\mu\nu_\mu$ and $\tau\nu_\tau$.\textsuperscript{2}
muon isolation requires that the transverse energy in the calorimeter within a cone of ∆R = 0.2 is below 4 GeV after excluding the muon energy deposits in the calorimeter. Furthermore, muon isolation requires that the scalar sum of the track transverse momenta in a cone of ∆R = 0.3 around the muon candidate is less than 2.5 GeV excluding the muon track. The efficiency of the muon isolation requirements depends weakly on the amount of pileup and is typically 85%.

Jets are reconstructed from clusters [36,39] built from energy deposits in the calorimeters using the anti-kt algorithm [40–42] with a radius parameter R = 0.4. The jets are calibrated using energy- and η-dependent calibration factors, derived from simulations, to the mean energy of stable particles inside the jets. Additional corrections to account for the difference between simulation and data are derived from in situ techniques [39].

Calibrated jets with pT > 25 GeV and |η| < 2.5 are selected. To reduce the background from other pp interactions within the same bunch crossing, the scalar sum of the pT of tracks matched to the jet and originating from the primary vertex must be at least 75% of the scalar sum of the pT of all tracks matched to the jet.

If there are jets within a cone of ∆R = 0.2 around a selected electron, the jet closest to the electron is discarded. This avoids double counting of electrons as jets. Finally, electrons are removed if they are within ∆R = 0.4 of a selected jet.

Jets originating from or containing b quarks are selected in the single-lepton final state, making use of the long lifetime of b hadrons. Variables using the properties of the secondary vertex and displaced tracks associated with the jet are combined by a neural network used for b-jet identification [43]. A working point with a 70% b-tagging efficiency is used to select t¯t events [44] in the single-lepton channel.

The magnitude of the missing transverse momentum (Emiss) is reconstructed from the vector sum of all calorimeter cell energies associated with topological clusters with |η| < 4.5 [45]. Contributions from the calorimeter energy clusters matched with either a reconstructed lepton or jet are corrected to the corresponding energy scale. The term accounting for the pT of any selected muon is included in the Emiss calculation.

IV. EVENT SELECTION

A. Dilepton channel

To select t¯t candidate events with leptonically decaying W bosons, two leptons of opposite charge (ℓ+ ℓ− = e+ e−, μ+ μ−, or e± µ±) and at least two jets are required. For the μ+ μ− final state, events containing a muon pair consistent with a cosmic-ray muon signature are rejected. In particular, events are rejected if two muon tracks are back to back in φ, they have the same sign pseudorapidity, and the point of closest approach to the primary vertex of each track is greater than 5 mm. Since the same-flavor lepton channels e+ e− and μ+ μ− suffer from a large background from the leptonic decays of hadronic resonances, such as the J/ψ and Y, the invariant mass of the two leptons, mℓℓ, is required to be larger than 15 GeV. A contribution from the Drell-Yan production of Z/γ∗ bosons in association with jets (Z/γ∗ + jets production) to these channels is suppressed by rejecting events where mℓℓ is close to the Z boson mass mZ; i.e., |mℓℓ − mZ| > 10 GeV is required. In addition, large missing transverse momentum, Emiss > 60 GeV, is required to account for the two neutrinos from the leptonic decays of the two W bosons. Events with at least two jets, |mℓℓ − mZ| < 10 GeV, and Emiss > 30 GeV are used as a control region to validate modeling of the spin observables (see Sec. VII A).

The e± μ± channel does not suffer from an overwhelming Drell-Yan background. Therefore the mℓℓ cut is not applied. To suppress the remaining background from Z/γ∗ × (→ ℓ− ℓ−) + jets production a cut on the scalar sum of the transverse energy of leptons and jets, H T > 130 GeV, is applied instead of the Emiss cut. The purity of the t¯t sample after the dilepton selection is about 85%.

B. Single-lepton channel

To select t¯t candidate events in the single-lepton final state, exactly one isolated lepton (electron or muon), at least four jets and high Emiss are required. The Emiss has to be larger than 30 GeV (20 GeV) in the e + jets (µ + jets) final state to account for the neutrino from the leptonic decay of a W boson. To suppress the contribution of QCD multijet events a cut on the scalar sum of transverse energy of leptons and jets, H T > 30 GeV, is applied in the e + jets final state while in the µ + jets final state, mT (W) + Emiss is required to be larger than 60 GeV. In both channels, at least one of the jets has to be identified as a b jet by the b-tagging algorithm, resulting in a 78% (e + jets) and 76% (µ + jets) pure t¯t sample.

V. SAMPLE COMPOSITION AND MODELING

After event selection, the sample is composed of t¯t signal and various backgrounds. In the following, the sample composition of the dilepton and single-lepton channels are discussed.

A. Dilepton channel

Backgrounds to same-flavor dilepton t¯t production arise from the Drell-Yan process with the Z/γ∗ boson decaying into e+ e− or µ+ µ−. In the e± μ±...
channel, one of the main backgrounds is due to $Z/\gamma^* + \text{jets}$ production with decays $Z/\gamma^* \rightarrow \tau^+\tau^-$, followed by leptonic decays of the $\tau$ leptons. Other backgrounds in dilepton channels are due to diboson production, associated production of a single top quark, and a $W$ boson ($Wt$), $t\bar{t}$ production with a single-lepton in the final state, single top quark production via s- or t-channel exchange of a $W$ boson, and the production of a $W$ boson in association with jets. The latter three processes contain nonprompt leptons that pass the lepton isolation requirement or misidentified leptons arising from jets. The contributions from these processes are estimated using data-driven methods.

Drell-Yan events are generated using the ALPGEN v2.13 [46] generator including leading-order (LO) matrix elements with up to five additional partons. The CTEQ6L1 parton distribution function (PDF) set [47] is used, and the cross section is normalized to the next-to-next-to-leading-order (NNLO) prediction [48]. Parton showering and fragmentation are modeled by HERWIG v6.520 [49], and the underlying event is simulated by JIMMY [50]. To avoid double counting of partonic configurations generated by both the matrix-element calculation and the parton-shower evolution, a parton-jet matching scheme (“MLM matching”) [51] is employed. The yields of dielectron and dimuon Drell-Yan events predicted by the Monte Carlo (MC) simulation are compared to the data in $Z/\gamma^* + \text{jets}$-dominated control regions. Correction factors are derived and applied to the predicted yields in the signal region, to account for the difference between the simulation prediction and data. The correction increases the $Z/\gamma^* \rightarrow e^+e^- + \text{jets}$ contribution by 3% and the $Z/\gamma^* \rightarrow \mu^+\mu^- + \text{jets}$ contribution by 13% relative to the prediction from simulation.

Single top quark background arises from the associated $Wt$ production, when both the $W$ boson emerging from the top quark and the $W$ boson from the hard interaction decay leptonically. This contribution is modeled with MC@NLO v4.01 [52–54] using the CT10 PDF set [55] and normalized to the approximate NNLO theoretical cross section [56].

Finally, the diboson backgrounds are modeled using ALPGEN v2.13 interfaced with HERWIG using the MRST LO** PDF set [57] and normalized to the theoretical calculation at next-to-leading-order (NLO) in QCD [58].

The background arising from the misidentified and nonprompt leptons (collectively referred to as “fake leptons”) is determined from data using the “matrix method,” which was previously used in the measurement described in Refs. [59,60].

The SM $t\bar{t}$ signal events are modeled using the MC@NLO v4.01 generator. Top quarks and the subsequent $W$ bosons are decayed conserving the spin correlation information. The decay products are interfaced with HERWIG, which showers the $b$ quarks and $W$ boson daughters, and with JIMMY to simulate multiparton interactions. A top quark mass of 172.5 GeV is assumed. The CT10 PDF set is used.

The generation chain can be modified such that top quarks are decayed by HERWIG rather than MC@NLO. In this case the top quark spin information is not propagated to the decay products, and therefore the spins between the top quarks are uncorrelated. This technique has a side effect that the top quarks in the uncorrelated case are treated as being on shell, and hence they do not have an intrinsic width. The effect of this limitation is found to be negligible.

All MC samples use a GEANT4-based simulation to model the ATLAS detector [61,62]. For each MC process, pileup is overlaid using simulated minimum-bias events from the PYTHIA generator. The number of additional $pp$ interactions is reweighted to the number of interactions observed in data.

In Table I the observed yields in data are compared to the expected background and the $t\bar{t}$ signal normalized to $\sigma_{tt} = 177_{-22}^{+10}$ pb calculated at NNLO in QCD including resummation of next-to-next-to-leading logarithmic soft gluon terms [63–67] with Top++ v2.0 [68] for a top quark mass of 172.5 GeV. A significantly lower yield in the dielectron channel compared to the dimuon channel is due to the stringent isolation criteria and higher $p_T$ cut on the electrons. The yield difference between $t\bar{t}$ signal with SM spin correlation and without spin correlation is found to be negligible in the $e^+\mu^+$ channel but not in the $e^+e^-$ or $\mu^+\mu^-$ channels. Here, the cut on the invariant mass of the dilepton system used to suppress backgrounds also preferentially selects uncorrelated $t\bar{t}$ pairs over correlated pairs. This is due to the fact that on average uncorrelated $t\bar{t}$ pairs have larger values of $\Delta p_T(\ell, \ell)$, which translates into larger values of $m_{\ell\ell}$ and therefore more events passing the $|m_{\ell\ell} - m_Z| > 10$ GeV selection cut. This effect is accounted for in the analysis.

---

**TABLE I.** Observed numbers of events in data compared to the expectation after the selection in the dilepton channels. Backgrounds and signal estimated from simulation are indicated with the (MC) suffix, whereas backgrounds estimated using data-driven techniques are indicated with a (DD) suffix. Quoted uncertainties include the statistical uncertainty on the yield and the uncertainty on the theoretical cross sections used for MC normalization. The uncertainty on the DD estimate is statistical only.

B. Single-lepton channel

In the single-lepton channel the main background is due to $W + \text{jets}$ production, where the $W$ boson decays leptonically. Other background contributions arise from $Z/\gamma^* + \text{jets}$ production, where the $Z$ boson decays into a pair of leptons and one of the leptons does not pass the selection requirements, from electroweak processes (diboson and single top quark production in the $s$, $t$ channel, and $Wt$ processes) and from multijets events, where a lepton from the decay of a heavy-flavor quark appears isolated or a jet mimics an electron. Additional background arising from $t\bar{t}$ events with two leptons in the final state, where one lepton lies outside the acceptance, is studied with MC@NLO MC simulation and treated as part of the signal. The diboson, single top quark and $Z/\gamma^* + \text{jets}$ backgrounds are estimated using simulated events normalized to the theoretical cross sections. The $W + \text{jets}$ events are generated with ALPGEN v2.13, using the CTEQ6L1 PDF set with up to five additional partons. Separate samples are generated for $W + b\bar{b}$, $W + c\bar{c}$, and $W + c$ production at the matrix-element level. The normalization of the $W + \text{jets}$ background and its heavy-flavor content are extracted from data by a method exploiting the $W + \text{jets}$ production charge asymmetry [59].

Table II shows the observed yields in data, compared to the expectation from the background and the $t\bar{t}$ signal. The expectation is in good agreement with the data.

the single-lepton final states, and the latter three variables are only used in the dilepton final state.

(i) The azimuthal opening angle, $\Delta \phi$, between the momentum directions of a top quark decay product and an antitop quark decay product in the laboratory frame. In the dilepton final state, $\Delta \phi(\ell^+, \ell^-)$, is explored. This observable is straightforward to measure and very sensitive because like-helicity gluon-gluon initial states dominate\cite{75}. It was used in Ref.\cite{35} to observe a nonvanishing spin correlation, consistent with the SM prediction. In the single-lepton channel, $\Delta \phi$ between the charged lepton momentum direction and either the down-type jet from $W$ boson decay, $\Delta \phi(l^+,d)$, or the $b$ jet from the hadronically decaying top quark, $\Delta \phi(l^+,b)$, are analyzed. Since this requires the identification of the jets from the $W$ boson and hadronically decaying top quark, full event reconstruction is necessary, making the measurement of $\Delta \phi$ in the single-lepton channel more challenging. Moreover, there is a need to identify the jet emerging from the down-type quark (see Sec. VII B for more details).

(ii) The "S ratio" of matrix elements $M$ for top quark production and decay from the fusion of like-helicity gluons $[g_R g_R + g_L g_L \rightarrow t \bar{t} \rightarrow (b \ell^+ \nu)(\bar{b} \ell^- \bar{\nu})]$ with SM spin correlation and without spin correlation at LO \cite{75},

$$
S = \frac{(|M_R|^2 + |M_L|^2)_{\text{corr}}}{(|M_R|^2 + |M_L|^2)_{\text{uncorr}}} = \frac{m_t^2 \{ (t \cdot \ell^+) (t \cdot \ell^-) + (\bar{t} \cdot \ell^+) (\bar{t} \cdot \ell^-) \} - m_t^2 (\ell^+ \cdot \ell^-)}{(t \cdot \ell^+) (t \cdot \ell^-)},
$$

(6)

The normalized distributions show predictions for SM spin correlation (red solid lines) and no spin correlation (black dotted lines).

![FIG. 1 (color online). Distributions of several observables for generated charged leptons from top quark decay and top quarks: (a) $\Delta \phi(\ell^+, \ell^-)$; (b) S ratio, as defined in Eq. (6); (c) $\cos(\theta_+)^\text{maximal} \cos(\theta_-)^\text{maximal}$, as defined in Eq. (2) in the helicity basis; (d) in the maximal basis. The normalized distributions show predictions for SM spin correlation (red solid lines) and no spin correlation (black dotted lines).]
where \( t^- \), \( \bar{t}^- \), \( \ell^+ \), and \( \ell^- \) are the 4-momenta of the top quarks and the charged leptons. Since the like-helicity gluon-gluon matrix elements are used for the construction of the \( S \) ratio, it is particularly sensitive to like-helicity gluon-gluon initial states. To measure this observable, and the two others described below, the top quark and the top antiquark have to be fully reconstructed.

(iii) The double differential distribution [Eq. (2)], where the top direction in the \( \ell \bar{\ell} \) rest frame is used as the spin quantization axis. The measurement of this distribution allows for a direct extraction of the spin correlation strength \( A_{\text{helicity}} \) [3], as defined in Eq. (3). The SM prediction is \( A_{\text{helicity}}^{\text{SM}} = 0.31 \), which was calculated including NLO QCD corrections to \( \ell \bar{\ell} \) production and decay and mixed weak-QCD corrections to the production amplitudes in Ref. [24]. MC@NLO, which includes NLO QCD corrections to \( \ell \bar{\ell} \) production but not to top quark decay, reproduces the same value after adding parton shower simulation by HERWIG.

(iv) The double differential distribution [Eq. (2)], using the “maximal” basis as the top spin quantization axis. For the gluon-gluon fusion process, which is a mixture of like-helicity and unlike-helicity initial states, no optimal axis exists where the spin correlation strength is 100%. This is in contrast to the quark-antiquark annihilation process where an optimal “off-diagonal” basis was first identified by Ref. [76]. However, event by event a quantization axis that maximizes spin correlation and is called the maximal basis can be constructed for the gluon fusion process [77]. A prediction for the \( \ell \bar{\ell} \) spin correlation using this observable is not yet available for 7 TeV \( pp \) collisions. Therefore, the prediction is calculated using the MC@NLO+HERWIG simulation resulting in \( A_{\text{maximal}}^{\text{SM}} = 0.44 \).

Figure 1 shows all four observables for \( l(a) \) generated charged leptons from top quark decay and \( l(b), l(c), l(d) \) top quarks in the dilepton final state, calculated with MC@NLO under the assumption of SM \( \ell \bar{\ell} \) spin correlation and no spin correlation, as defined in Sec. V.

The measurement of the four variables in the dilepton final state does not comprise redundant information. It can be shown that the hadronic \( \ell \bar{\ell} \) production density matrices at tree level can be decomposed into different terms analyzing top quark spin-independent effects, top quark polarization, and \( \ell \bar{\ell} \) spin correlations [78]. Using rotational invariance, these terms can be structured according to their discrete symmetry properties. In this way four independent C-even and P-even spin correlation coefficients that are functions of the partonic center-of-mass energy and the production angle are introduced. The four observables investigated here depend on different linear combinations of these four coefficient functions.

In the single-lepton final state, \( \Delta \phi(\ell^-,d) \) and \( \Delta \phi(\ell^-,b) \) are used in the analysis. Their distributions are shown in Fig. 2 for generated leptons and quarks and are identical in the absence of spin correlation. The presence of spin correlation causes a split into two distributions such that the \( \Delta \phi(\ell^-,b) \) distribution becomes steeper while the trend is opposite for \( \Delta \phi(\ell^-,d) \). At parton level the separation between the distribution with SM spin correlation and without spin correlation for \( \Delta \phi(\ell^-,d) \) is similar to the one for \( \Delta \phi(\ell^-,e) \) in the dilepton channel while the separation is significantly smaller for \( \Delta \phi(\ell^-,b) \).

FIG. 2 (color online). Distribution of \( \Delta \phi \): (a) between lepton and \( d \) quark; (b) between lepton and \( b \) quark, for generated top quark decay products. The normalized distributions show predictions for SM spin correlation (red solid lines) and no spin correlation (black dotted lines).
VII. MEASUREMENT PROCEDURE

After selecting a $t\bar{t}$-enriched data sample and estimating the signal and background composition, the spin correlation observables, as defined in Sec. VI, are measured and used to extract the strength of the $t\bar{t}$ spin correlation.

In the dilepton final state, the $\Delta \phi (\ell, \ell)$ observable is the absolute value of the difference in $\phi$ of the two leptons; i.e. it is measured in the laboratory frame. Figures 3(a) and 4(a) show this distribution in the $e^+e^-$ and $\mu^+\mu^-$ channels, respectively, in a control region dominated by $Z/\gamma^* + \text{jets}$ background. Figures 3(b), 3(c), and 3(d) show the $S$ ratio, $\cos (\theta_+ \cos (\theta_+))$, and $\cos (\theta_+ \cos (\theta_-))$ observables, respectively, in the helicity basis, and Figures 3(e), 3(f), and 3(g) show the same observables in the maximal basis. The $Z/\gamma^* + \text{jets}$ background is normalized to the data in the control region. The contributions from single top and $Z \rightarrow \tau^+\tau^- + \text{jets}$ are not included in the legend as their contribution in this region is negligible. The uncertainties shown in the ratio are the systematic uncertainty due to the modeling of the $Z$ transverse momentum, which is a dominant effect in this control region.
In the single-lepton final state, two observables for the spin correlation measurement are used, $\Delta \phi(\ell, d)$ and $\Delta \phi(\ell, b)$, that both require event reconstruction to identify the jets from $W$-boson and top quark decay. Furthermore, a larger sensitivity to the modeling of the kinematics of $t \bar{t}$ events requires a somewhat different approach than in the...
dilepton final state: instead of fitting $\Delta \phi(\ell, d)$ and $\Delta \phi(\ell, b)$ separately, a fit to the combination of both observables is used.

A. Kinematic reconstruction of the $t\bar{t}$ system in the dilepton final state

The two neutrinos from $W$-boson decays in dilepton final states cannot be measured but can only be inferred from the measured missing transverse momentum in the event. Since only the sum of the missing transverse momenta of the two neutrinos is measured, the system is underconstrained.

In this analysis a method known as the “neutrino weighting technique” [79] is employed. To solve the event kinematics and assign the final-state objects to the decay products of the top quark and top antiquarks, the invariant mass calculated from the reconstructed charged lepton and the assumed neutrino has to correspond to the $W$-boson mass, and the invariant mass of the jet-lepton-neutrino combination is constrained to the top quark mass. To fully solve the kinematics, the pseudorapidities $\eta_1$ and $\eta_2$ of the two neutrinos are sampled from a fit of a Gaussian function to the respective distributions in a simulated sample of $t\bar{t}$ events. It was verified that the $\eta_1$ and $\eta_2$ distributions in $t\bar{t}$ events do not change for different $t\bar{t}$ spin correlation strengths. Fifty values are chosen for each neutrino $\eta$, with $-4 < \eta_1, \eta_2 < 4$ taken independently of each other.

By scanning over all $\eta_1$ and $\eta_2$ configurations taken from the simulation, all possible solutions of how to assign the charged leptons, neutrinos, and jets to their parent top quarks are accounted for. In addition, the energies of the reconstructed jets are smeared according to the experimental resolution [80], and the solutions are recalculated for every smearing step. If no solution is found, the event is discarded. Around 95% of simulated $t\bar{t}$ events have at least one solution. This fraction is considerably lower for the backgrounds, leading to an increase by 25% in the signal-to-background ratio when requiring at least one solution. Each solution is assigned a weight, defined by

$$w = \prod_{i=x,y} \exp\left(\frac{-(E_{i,\text{miss}}^{\text{calc}} - E_{i,\text{miss}}^{\text{obs}})^2}{2(\sigma_{E_{i,\text{miss}}^{\text{obs}}})^2}\right).$$

where $E_{i,\text{miss}}^{\text{calc}}$ ($E_{i,\text{miss}}^{\text{obs}}$) is the calculated (observed) missing transverse momentum component in the $x$ or $y$ direction. Solutions that fit better to the expected $t\bar{t}$ event kinematics are assigned a higher weight. The measured resolution of the missing transverse momentum $\sigma_{E_{i,\text{miss}}^{\text{obs}}}$ is taken from Ref. [45] as a function of the sum of the transverse energy in the event. For example, for an event with a total sum of transverse momentum of 100 GeV, the resolution is taken to be 6.6 GeV. The weights of all solutions define a weight distribution for each observable per event. For each event, the weighted mean value of the respective observable is used for the measurement.

Figures 3(b)–3(d) and 4(b)–4(d) show distributions of spin correlation observables that use the $t\bar{t}$ event reconstruction with the neutrino weighting method. For the $e^+e^-$ and $\mu^+\mu^-$ channels, in a control region dominated by $Z/\gamma^* + \text{jets}$ production, the $S$ ratio and $\cos(\theta_+) \cos(\theta_-)$ in two different spin quantization bases are presented. Good agreement between data and the prediction is observed confirming a reliable description of observables sensitive to $t\bar{t}$ spin correlations with and without $t\bar{t}$ event reconstruction in the Drell-Yan background.

B. Kinematic reconstruction of the $t\bar{t}$ system in the single-lepton channel

In the single-lepton events, there is one missing neutrino from the $W \to \ell\nu$ decay. Therefore, the $W$-boson mass and the top quark mass can be used as constraints to solve the kinematics and to assign the reconstructed objects (jets, leptons, and $E_{\text{miss}}^{\text{jet}}$) to the corresponding partons (quarks, leptons, and the neutrino). The main challenge for the event reconstruction in this final state is the presence of at least four jets, providing a large number of possible permutations when assigning objects to partons.

To perform the kinematic reconstruction, the Kinematic Likelihood Fitter (KLFitter) algorithm [81] is applied. The likelihood function is defined as a product of individual likelihood terms describing the kinematics of the $t\bar{t}$ signature including constraints from the masses of the two $W$ bosons and the two top quarks. Detector resolutions for energy measurements are described in terms of transfer functions that map initial parton kinematics to those of reconstructed jets and leptons. The transfer functions are derived for electrons, muons, light-quark ($u, d, s, c$) jets, and $b$-quark jets, using a simulated $t\bar{t}$ sample generated with MC@NLO, and are parametrized in $p_T$ (for muons) or energy in several $\eta$ regions of the detector. The angular variables of each reconstructed object are measured with a negligible uncertainty.

The likelihood is maximized taking into account all possible permutations of the objects. The maximized likelihood of each permutation is extended to a normalized event probability by adding information from $b$-jet identification. This enhances the probability to choose the correct assignment of the reconstructed objects. The likelihood itself is invariant under the exchange of jets from down-type and up-type quarks from the $W$-boson decay. To enhance the probability to correctly assign the jets to down-type and up-type quarks from the $W$-boson decay, two additional quantities are incorporated into the likelihood. The first quantity is the weight assigned to the jet by the $b$-jet tagging algorithm. This takes advantage of the fact that 50% of the $W$-boson decays contain charm quarks, which have higher $b$-tag weights than other light quarks. The second quantity is the reconstructed jet $p_T$. Because of the $V-A$ structure of the $W$-boson decay, down-type jets have on average a lower $p_T$ than up-type jets. A two-dimensional
probability distribution of the reconstructed jet \( p_T \) and the weight assigned to a jet by the \( b \)-jet tagging algorithm are used in the event probability. Figure 5 shows the event probability distribution for the permutation with the highest value in the \( \mu^+ \) jets channel.

If the \( p_T \) and \( b \)-tagging weights of the two light jets are similar, no additional separation power is obtained and both permutations have an equal event probability of not larger than 0.5. In case the event probability reaches values above 0.5, one permutation matches the model better than all others, implying additional separation power between the two light jets. For the construction of the \( \Delta \phi(\ell, d) \) and \( \Delta \phi(\ell, b) \) observables, the permutation with the highest event probability is chosen.

Figure 6 shows distributions of \( \Delta \phi(\ell, d) \) and \( \Delta \phi(\ell, b) \) after selection and \( t\bar{t} \) kinematic reconstruction for the SM spin correlation and no spin correlation scenarios in a subchannel of single-lepton events containing one muon and five jets, two of which are \( b \) tagged. One can see a significant deterioration of the separation between the two distributions compared to the parton-level results in Fig. 2. This is mainly due to misreconstruction of the top quarks which leads to a loss of the spin information. Because of a more reliable identification of \( b \)-quark jets compared to \( d \)-quark jets, the separation becomes comparable between the \( \Delta \phi(\ell, d) \) and \( \Delta \phi(\ell, b) \) observables in the single-lepton final state, motivating the use of both observables for the measurement.

C. Extraction of spin correlation

To extract the spin correlation strength from the distributions of the respective observables in data, templates are constructed and a binned maximum likelihood fit is performed. For each background contribution, one template for every observable is constructed. For the \( t\bar{t} \) signal, one template is constructed from a MC@NLO sample with SM spin correlation and another using MC@NLO without spin correlation. The templates are fitted to the data. The predicted number of events per template bin \( i \) is written as a function of the coefficient \( f_{SM} \) as

\[
m^i = f_{SM} \times m^i_{A=SM}(\sigma_{t\bar{t}}) + (1 - f_{SM}) \times m^i_{A=0}(\sigma_{t\bar{t}}) + \sum_{j=1}^{N_{bkg}} m^i_j,
\]

(8)

FIG. 5 (color online). Event probability distribution in the \( \mu^+ \) jets channel for the most likely permutation.

FIG. 6 (color online). Distributions of \( \Delta \phi(\ell, d) \) between (a) the lepton and the jet from the down-type quark and (b) \( \Delta \phi(\ell, b) \) between the lepton and the jet from the \( b \) quark after event selection and reconstruction for MC@NLO samples with SM spin correlation and no spin correlation.
where \( m_{A=\text{SM}}^i (\sigma_{A}) \) and \( m_{A=0}^i (\sigma_{A}) \) is the predicted number of signal events in bin \( i \) for the signal template obtained with the SM MC@NLO sample and with the MC@NLO sample with spin correlation turned off, respectively, and \( \sum_{j=1}^{N_{\text{bkg}}} m_j \) is the sum over all background contributions \( N_{\text{bkg}} \). To reduce the influence of systematic uncertainties sensitive to the normalization of the signal, the \( \bar{t}t \) cross section \( \sigma_{\bar{t}t} \) is included as a free parameter in the fit.

The negative logarithm of the likelihood function \( L \)

\[
L = \prod_{i=1}^{N} \mathcal{P}(n'_i, m^i)
\]  

is minimized with \( \mathcal{P}(n'_i, m^i) \) representing the Poisson probability to observe \( n'_i \) events in bin \( i \) with \( m^i \) events expected. The number of bins \( N \) used for the fit depends on the variable and the channel.

To maximize sensitivity in the single-lepton channel by taking advantage of different \( \bar{t}t \) signal purities, the preselected sample is split into subsamples of different lepton flavors with exactly one and more than one \( b \)-tagged jet and exactly four and at least five jets, thus giving eight subchannels in the likelihood fit. Moreover, since the power of the two variables \( \Delta \phi(\ell, b) \) and \( \Delta \phi(\ell, d) \) to discriminate between the SM spin correlation and no spin correlation scenarios is comparable, and the correlation between them is at most 10\%, both are included in the fit as independent subchannels. This approach not only allows an effective doubling of the information used in the fit but also takes advantage of the opposite behavior of the ratios between the spin correlation and no spin correlation scenarios in the two observables. This in turn leads to opposite trends with respect to the signal-modeling systematic uncertainties resulting in significant cancellation effects.

To demonstrate a reduced sensitivity of the simultaneous fit using \( \Delta \phi(\ell, b) \) and \( \Delta \phi(\ell, d) \) to the choice of the signal model, pseudodata \( \bar{t}t \) events simulated with POWHEG interfaced to HERWIG with spin correlation included \((f_{\text{SM}} = 1)\) were generated and the fit was performed using the default templates, simulated with MC@NLO interfaced to HERWIG. The measured \( f_{\text{SM}} \) is \( f_{\text{SM}} = 1.26 \pm 0.14(\text{stat}) \) when using the \( \Delta \phi(\ell, d) \) observable, and \( f_{\text{SM}} = 0.64 \pm 0.18(\text{stat}) \) for \( \Delta \phi(\ell, b) \). Fitting both distributions simultaneously resulted in a value of \( f_{\text{SM}} \) compatible with the true value, namely \( f_{\text{SM}} = 1.02 \pm 0.11(\text{stat}) \). The difference is explained to a large extent by the difference of the top quark \( p_T \) distributions in POWHEG and MC@NLO. The recent measurements by the ATLAS [82] and CMS [83] Collaborations indicate that the top quark \( p_T \) distributions vary between the generators and that the top quark \( p_T \) distribution in data is better described by POWHEG interfaced with HERWIG [82]. Ensemble tests performed using templates produced after reweighting the top quark \( p_T \) in the MC@NLO sample to the distribution in POWHEG show a reduced difference between the results obtained using different analyzers: \( f_{\text{SM}} = 1.13 \pm 0.14(\text{stat}) \) when using \( \Delta \phi(\ell, d) \), \( f_{\text{SM}} = 0.77 \pm 0.18(\text{stat}) \) for \( \Delta \phi(\ell, b) \), and \( f_{\text{SM}} = 0.99 \pm 0.11(\text{stat}) \) if the simultaneous fit to both observables is performed. Figures 7(a) and 7(b) demonstrate the effect of top quark \( p_T \) reweighting on the

</table>
A number of systematic uncertainties affecting the $t\bar{t}$ modeling are considered. Systematic uncertainty associated with the choice of factorization and renormalization scales in MC@NLO is evaluated by varying the default scales by a factor of 2 up and down simultaneously. The uncertainty due to the choice of parton shower and hadronization model is determined by comparing two alternative samples simulated with the POWHEG (HQV v4) [85] generator interfaced with PYTHIA 6.425 [86] and HERWIG v6.520. The uncertainty on the amount of initial- and final-state radiation (ISR and FSR) in the simulated $t\bar{t}$ sample is assessed by comparing ALPGEN, showered with PYTHIA, with varied amounts of initial- and final-state radiation. The size of the variation is compatible with the recent measurements of additional jet activity in $t\bar{t}$ events [87]. The uncertainty due to the choice of the underlying event model is estimated by comparing a POWHEG-generated sample showered with PYTHIA with the PERUGIA 2011 tune to one with the PERUGIA 2011 MPhys tune [88]. The latter is a variation of the PYTHIA 2011 tune with more semihard multiple parton interactions. The impact of the color reconnection model of the partons that enter hadronization is assessed by comparing samples generated with POWHEG and showered by PYTHIA with the PERUGIA 2011 tune and the PERUGIA 2011 NOCR tune [88]. To investigate the effect of the choice of PDF used in the analysis, the uncertainties from the nominal CT10 PDF set and from the NNPDF2.3 [89] and MSTW2008 [90] NLO PDF sets are considered, and the envelope of these uncertainties is taken as the uncertainty estimate. The dependence of the measured $f_{SM}$ on the top quark mass is evaluated by changing the value of 172.5 GeV used in the simulation and performing a linear fit of the dependency of the considered observable on the top quark mass in the mass range $172.5 \pm 5$ GeV.

Uncertainties on the backgrounds (quoted as “Background” in Table III), evaluated using simulation, arise from the limited knowledge of the theoretical cross sections for single top, diboson, and $Z \rightarrow \tau^+\tau^-$ production, from the modeling of additional jets in these samples and from the integrated luminosity. The uncertainty of the latter amounts to $\pm 1.8\%$ [91]. Systematic uncertainties on the $Z \rightarrow e^+e^-$ and $Z \rightarrow \mu^+\mu^-$ backgrounds result from the uncertainty of their normalization to data in control regions and modeling of the $Z$-boson transverse momentum. It was checked that these uncertainties cover the small differences between data and prediction seen in Figs. 3(a) and 4(a). The uncertainty on the $W+\text{jets}$ background in the single-lepton channel arises from the normalization uncertainty and from the uncertainty on the flavor composition given by the charge asymmetry method. The uncertainty on the fake lepton background (“Fake leptons” in Table III) arises mainly from uncertainties on the measurement of lepton misidentification rates in different control samples.

Finally, an uncertainty on the method to extract the spin correlation strength arises from the limited size of the MC samples used to create the templates.

As discussed in Sec. VII, top quark $p_T$ modeling has an effect on $f_{SM}$. The effect on $f_{SM}$ of reweighting of the top quark $p_T$ to match the distribution in unfolded data is listed separately in Sec. VII C. To avoid double counting, the uncertainty due to the choice of parton shower and hadronization model is evaluated after the top quark $p_T$ distribution in POWHEG+PYTHIA is corrected to be consistent with POWHEG+HERWIG.

**IX. RESULTS**

In the following, the results for the spin correlation measurements in the dilepton and single-lepton final states are discussed.

### A. Dilepton channel

For each of the four observables, the maximum likelihood fit in each of the three individual channels ($e^+e^-$, $e^\pm\mu^\mp$, and $\mu^+\mu^-$) and their combination is performed. The observable with the largest statistical separation power between the no spin correlation and the SM spin correlation hypotheses is $\Delta \phi$. The measured values of $f_{SM}$ for $\Delta \phi(\ell, \ell')$, the $S$ ratio, and $\cos(\theta_+ \cos(\theta_-)$ in the helicity and maximal bases are summarized in Table IV. The systematic uncertainties and their effect on the measurement of $f_{SM}$ in the dilepton channel are listed in Table III. Because of the different methods of constructing the four observables, they have different sensitivities to the various sources of systematic uncertainty and to the various physics effects. Some of the given uncertainties are limited by the size of the samples used for their extraction. The dependence of $f_{SM}$ on the top quark mass $m_t$ is parametrized as $\Delta f_{SM} = -1.55 \times 10^{-3}(m_t/\text{GeV} - 172.5)$ for $\Delta \phi(\ell, \ell')$, $\Delta f_{SM} = -0.010(m_t/\text{GeV} - 172.5)$ for the $S$ ratio, $\Delta f_{SM} = 0.015(m_t/\text{GeV} - 172.5)$ for $\cos(\theta_+ \cos(\theta_-)$ in

the helicity basis, and $\Delta f_{SM} = 0.016(m_t/\text{GeV} - 172.5)$ for $\cos(\theta_+\cos(\theta_-)$ in the maximal basis.

Figure 8 shows the distribution of the four observables in the data, the prediction for SM spin correlation and no spin correlation, and the result of the fit.

The analysis of the $\cos(\theta_+\cos(\theta_-)$ observable allows a direct measurement of the spin correlation strength $A$, because $A$ is defined by the $\cos(\theta_+\cos(\theta_-)$ distribution according to Eq. (2). This becomes obvious in Eqs. (4) and (5), which show that the expectation value of $\cos(\theta_+\cos(\theta_-)$ is equal to $A$ modulo constant factors. Therefore, the extraction of $f_{SM}$ using the full distribution in a template method is equivalent to extracting the spin correlation in the respective spin quantization basis $A_{\text{measured}}$. The relation is given by

$$A_{\text{measured}} = f_{SM} A_{\text{SM}}^\text{basis},$$

Distributions of (a) $\Delta \phi(l^+, l^-)$, (b) $S$ ratio, (c) $\cos(\theta_+\cos(\theta_-)$ in the helicity basis, and (d) $\cos(\theta_+\cos(\theta_-)$ in the maximal basis in the dilepton final state. The result of the fit to data (blue lines) is compared to the templates for background plus $t\bar{t}$ signal with SM spin correlation (red dashed lines) and without spin correlation (black dotted lines). The bottom panel shows the ratio of the data (black points), the best fit (blue solid lines) and the no spin prediction to the SM prediction.
with the SM predictions being $A^{SM}_{\text{hel}} = 0.31$ and $A^{SM}_{\text{max}} = 0.44$, respectively, as discussed in Sec. VI.

Combining all three final states in the measurement of $\cos(\theta_+)$ in the helicity basis, a direct measurement of $A^{\text{measured}}_{\text{hel}} = 0.37 \pm 0.06 \text{ (stat)} \pm 0.08 \text{ (syst)}$ is derived, which is in good agreement with the SM value of $A^{SM}_{\text{hel}} = 0.31$.

The combined result using $\cos(\theta_+) \cos(\theta_-)$ in the maximal basis gives a direct measurement of $A^{\text{measured}}_{\text{max}} = 0.37 \pm 0.06 \text{ (stat)} \pm 0.08 \text{ (syst)}$, in good agreement with the SM value of $A^{SM}_{\text{max}} = 0.44$.

The analysis of $\Delta \phi(\ell, \ell)$ and the $S$ ratio allows an indirect extraction of $A$ under the assumption that the $t\bar{t}$ sample is composed of top quark pairs as predicted by the SM, either with or without spin correlation, but does not contain contributions beyond the SM. In that case, a change in the fraction $f_{SM}$ will lead to a linear change of $A$ according to Eq. (2). This has been verified in pseudoexperiments. Under these conditions, the measured $f_{SM}$ can be translated into values of $A^{\text{measured}}_{\text{hel}}$ via Eq. (10), giving $A^{\text{measured}}_{\text{hel}} = 0.37 \pm 0.03 \text{ (stat)} \pm 0.06 \text{ (syst)}$ and $A^{\text{measured}}_{\text{max}} = 0.52 \pm 0.04 \text{ (stat)} \pm 0.08 \text{ (syst)}$. These results are limited by systematic uncertainties, in particular by uncertainties due to signal modeling. The influence of the dominant systematic uncertainties in the previous ATLAS measurement performed on a smaller data set (2.1 fb$^{-1}$), giving $A_{\text{hel}} = 0.40^{+0.09}_{-0.08} \text{ (stat) syst}$ [35], has been reduced due to a better model of the fake lepton background and improved understanding of the jet energy scale. The two results are in agreement with each other.

The analysis of the $S$ ratio results in $A^{\text{measured}}_{\text{hel}} = 0.27 \pm 0.03 \text{ (stat)} \pm 0.04 \text{ (syst)}$ and $A^{\text{measured}}_{\text{max}} = 0.38 \pm 0.05 \text{ (stat)} \pm 0.06 \text{ (syst)}$.

All results are summarized in Table V. Within uncertainties, all values are in agreement with the SM prediction and with each other.

### B. Single-lepton channel

The measured value of $f_{SM}$ using the simultaneous fit to the $\Delta \phi(\ell, d)$ and $\Delta \phi(\ell, b)$ variables in the single-lepton channel is $f_{SM} = 1.12 \pm 0.11 \text{ (stat)} \pm 0.22 \text{ (syst)}$. Again, under the assumption that there is only SM $t\bar{t}$ spin correlation, vanishing $t\bar{t}$ spin correlation, or any mixture of both, this results in an indirect extraction of $A^{\text{measured}}_{\text{hel}} = 0.35 \pm 0.03 \text{ (stat)} \pm 0.08 \text{ (syst)}$. The systematic uncertainties and their effect on the measurement of $f_{SM}$ are listed in Table VI. Part of the detector modeling uncertainties were determined using nuisance parameters, corresponding to the uncertainties on lepton identification, $b$-jet tagging, and jet energy calibration (denoted “Detector modeling I” in Table VI). Uncertainties due to lepton reconstruction, jet reconstruction and resolution, and multi-jet background shape are evaluated using ensemble tests and are included in the “Detector modeling II” entry. In the single-lepton channel, the main systematic uncertainty arises from parton showering and fragmentation. The parametrization of $f_{SM}$ versus the top quark mass is $\Delta f_{SM} = 0.024(m_t/\text{GeV}) - 172.5$.

Figure 9 shows the observables including the result of the fit to data.

### TABLE VI. Systematic uncertainties on $f_{SM}$ determined from the simultaneous fit to $\Delta \phi(\ell, d)$ and $\Delta \phi(\ell, b)$. Uncertainty on the background normalization is included in the statistical uncertainty of the fit while uncertainty on the background shape is included into “Detector modeling I” and “Detector modeling II.” The detector modeling uncertainties are split into nuisance parameter uncertainties (I) and uncertainties evaluated via ensemble tests (II).

FIG. 9 (color online). Distributions of (a) \( S(\ell,d) \) and (b) \( S(\ell,b) \) in the single-lepton final state. The result of the fit to data (blue lines) is compared to the templates for background plus \( t\bar{t} \) signal with SM spin correlation (red dashed lines) and without spin correlation (black dotted lines). The bottom panel shows the ratio of the data (black points), of the best fit (blue solid lines) and of the no spin prediction to the SM prediction.

Figure 10 summarizes the \( f_{SM} \) values measured using various observables in the dilepton and single-lepton final states. All measurements agree with the SM prediction of \( f_{SM} = 1 \).

X. CONCLUSIONS

The \( t\bar{t} \) spin correlation in dilepton and single-lepton final states is measured utilizing ATLAS data, corresponding to an integrated luminosity of 4.6 fb\(^{-1}\), recorded in proton-proton scattering at the LHC at a center-of-mass energy of 7 TeV.

In dilepton final states, four observables are used with different sensitivities to like-helicity gluon-gluon initial states and unlike-helicity gluon-gluon or \( q\bar{q} \) initial states. For the first time, the measurement of \( t\bar{t} \) spin correlation is performed using the \( S \) ratio. Also, a direct measurement of the spin correlation strengths \( A_{\text{helicity}} \) and \( A_{\text{maximal}} \) is performed using \( \cos \theta_c \cos \theta_\omega \) in the helicity and maximal bases, respectively. The measurement in the maximal basis is performed for the first time resulting in \( A_{\text{measured}}^{\text{maximal}} = 0.36 \pm 0.10 \) (stat+syst).

In the dilepton channel, the measurement of \( t\bar{t} \) spin correlation using the azimuthal angle between the charged leptons, \( \Delta\phi \), gives \( f_{SM} = 1.19 \pm 0.19 \) (stat+syst). In the single-lepton channel, the \( t\bar{t} \) spin correlation strength is measured for the first time at the LHC using a simultaneous fit to the azimuthal angle between charged lepton and \( d \)-quark \( \Delta\phi(\ell,d) \) and between charged lepton and \( b \)-quark \( \Delta\phi(\ell,b) \). The result is \( f_{SM} = 1.12 \pm 0.24 \) (stat+syst). These measurements in the dilepton and single-lepton channels are in good agreement with the SM predictions.
ACKNOWLEDGMENTS

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently. We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWFW and FWF, Austria; ANAS, Azerbaijan; STC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DFKI, ERC and NSRF, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNSF, Georgia; BMBF, DFG, HGF, MPG and MPG and AvH Foundation, Germany; GSRT and NSRF, Greece; IFN, INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; BRF and RCN, Norway; MNI and NCN, Poland; GRICES and FCT, Portugal; MNE/IFA, Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MIZS, Slovenia; DST/NRF, South Africa; MINECO, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America. The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.
