I. INTRODUCTION

Discovering a nonzero electric dipole moment (EDM) of the neutron would have far-reaching implications. Indeed, the existence of an EDM for a simple spin-1/2 particle implies the violation of time-reversal invariance and therefore the violation of CP symmetry. So far, the observed $T$ and $CP$ violation in nature is entirely accounted for by the Kobayashi-Maskawa mechanism. This mechanism predicts an unmeasurably small value for the EDMs of all subatomic particles. Therefore, electric dipole moments are sensitive probes of new physics beyond the standard model of particle physics. In fact, new CP violating interactions are needed to explain the generation of the matter-antimatter asymmetry in the early Universe. Thus, the motivation to search for the neutron EDM (nEDM) lies at the interface between particle physics and cosmology. The subject is treated in the classic book [1].

Magnetic-field uniformity is of the utmost importance in experiments to measure the electric dipole moment of the neutron. A general parametrization of the magnetic field in terms of harmonic polynomial modes is proposed, going beyond the linear-gradients approximation. We review the main undesirable effects of nonuniformities: depolarization of ultracold neutrons and Larmor frequency shifts of neutrons and mercury atoms. The theoretical predictions for these effects were verified by dedicated measurements with the single-chamber neutron electric-dipole-moment apparatus installed at the Paul Scherrer Institute.

separated oscillatory fields. By comparing the neutron precession frequency in parallel and antiparallel fields, one extracts

\[ d_n = \pi \hbar (f_{n,1} - f_{n,1'}) / 2E. \]

In these experiments, besides maximizing the number of stored ultracold neutrons, the control of the magnetic field is the most important experimental challenge. The time fluctuations of the magnetic field must be minimized and monitored, and the magnetic field should be sufficiently uniform. Even if external perturbations of the magnetic field are attenuated by several layers of shielding, residual time variations of the \( B_0 \) field still need to be monitored in real time. To this aim, the experiment [14,15] uses a comagnetometer: Spin-polarized \(^{199}\text{Hg} \) atoms fill the chamber, colocated with the stored ultracold neutrons [16,17]. The time-averaged precession frequency of the mercury spins \( f_{\text{Hg}} \) over each measurement cycle is used to correct for the drifts of the magnetic field through the relation \( f_{\text{Hg}} = \gamma_{\text{Hg}} / (2\pi) B_0 \), where \( \gamma_{\text{Hg}} \) is the gyromagnetic ratio.

Not only must the field be stable, with its time variations precisely monitored, it also needs to be extremely uniform over a large volume. As will be explained later, a field uniformity at a level better than 1 nT must be achieved inside the chamber. For the purpose of tuning and characterizing the field uniformity, the comagnetometer alone is not sufficient. One must therefore rely upon offline mapping of the magnetic field in the inner part of the apparatus, and/or upon an array of magnetometers around the chamber measuring the field in real time.

In this paper, we discuss the effects of magnetic-field nonuniformities in experiments measuring the neutron EDM with stored ultracold neutrons. Specific concerns associated with the use of an atomic comagnetometer are also dealt with in detail. In particular, the formalism described in the paper is adequate to discuss the systematic effects in the experiment that was in operation at the Paul Scherrer Institute (PSI) during the period 2009–2017. The apparatus was an upgraded version of the one previously installed at the ILL that produced the current lowest experimental limit. However, we aim at a general treatment of the subject—whenever possible—so that the results are of interest for other past experiments such as [18] as well as for the future experiments currently in development at the U.S. Spallation Neutron Source [19], FRMII/ILL [20], TRIUMF [21], PNPI [22], LANL, and PSI [23].

In the first part we present a general parametrization of the field in terms of a polynomial expansion. It goes beyond the usual description in terms of linear gradients, a refinement that becomes necessary to quantify the systematic effects at the current level of sensitivity. In the second and third parts, we discuss the effects of field nonuniformities on the statistical and systematic precision, respectively. Dedicated measurements were performed to corroborate the theoretical predictions for these effects.

This paper has two companion papers and should be read as the first part of a trilogy. The second part will describe the array of atomic cesium magnetometers developed for the PSI nEDM experiment and the methods to optimize \textit{in situ} the field uniformity. The third part will present the offline characterization of the magnetic-field uniformity in the apparatus with an automated field-mapping device.

II. HARMONIC POLYNOMIAL EXPANSION OF THE MAGNETIC FIELD

In modern nEDM experiments a weak magnetic field \( B_0 \approx 1 \mu \text{T} \) is applied in a volume of about a cubic meter or more. In the context of this paper the field can be considered to be purely static. The field \( B(x, y, z) \approx B_0 \vec{e}_z \) is very uniform, but the remaining nonuniformities have paramount consequences. An adequate description of the nonuniformities is needed to discuss these consequences.

We construct a polynomial expansion (in terms of the Cartesian coordinates \( x, y, z \)) of the magnetic-field components, in the form

\[ \vec{B}(\vec{r}) = \sum_{l,m} \frac{G_{l,m}(\vec{r})}{\Pi_{l,m}(\vec{r})} \]  

where the functions (or \textit{modes}) \( \Pi_{l,m} \) are harmonic polynomials in \( x, y, z \) of degree \( l \) and \( G_{l,m} \) are the expansion coefficients.

The polynomials, however, cannot be chosen arbitrarily, since the magnetic field must satisfy Maxwell’s equations:

\[ \vec{\nabla} \cdot \vec{B} = 0 \quad \text{and} \quad \vec{\nabla} \times \vec{B} = 0, \]

in a region with neither currents nor magnetization. This requirement is equivalent to enforcing that the field is the gradient of a magnetic potential, \( \vec{B}(\vec{r}) = \vec{\nabla} \Sigma(\vec{r}) \), with the potential satisfying Laplace’s equation \( \Delta \Sigma = 0 \). Solutions of Laplace’s equation are called harmonic functions. Therefore, all possible polynomial field components of degree \( l - 1 \) are exactly obtained by taking the gradient of all possible harmonic polynomials of degree \( l \). The so-called solid harmonics, expressed in spherical coordinates as

\[ r^l Y_{l,m}(\theta, \phi) = \frac{2l+1}{4\pi} \frac{(l-m)!}{(l+m)!} j^l P^m_l (\cos \theta) e^{im\phi}, \]

form a basis of complex homogeneous polynomials, with \( l \) the degree of the polynomial and \( m \) an integer in the range \(-l \leq m \leq l\). In this form \( Y_{l,m} \) are the standard spherical harmonics and \( P^m_l \) are the associated Legendre polynomials (listed in Table I).

To construct our basis, we need to take the real and imaginary parts of the complex polynomials. In addition, we use a different and convenient normalization of the polynomials and define

\[ \Sigma_{l,m} = C_{l,m}(\phi) r^l P^m_l (\cos \theta), \]

with

\begin{align*}
C_{l,m}(\phi) &= \frac{(l-1)!(-2)^{|m|}}{(l+|m|)!} \cos(|m|\phi) \quad \text{for} \quad m \geq 0, \\
C_{l,m}(\phi) &= \frac{(l-1)!(-2)^{|m|}}{(l+|m|)!} \sin(|m|\phi) \quad \text{for} \quad m < 0.
\end{align*}

Finally, the modes are obtained by calculating the gradient of the magnetic potential:

\[ \Pi_{l,m} = \partial_{\phi} \Sigma_{l+1,m}, \quad \Pi_{l,0} = \partial_{\phi} \Sigma_{l,0}, \quad \Pi_{l,m} = \partial_{\phi} \Sigma_{l+1,m}. \]

Note that \( l \) always refers to the degree of the polynomial, and therefore \( \Pi_{l,m} \) is obtained from the magnetic potential \( \Sigma_{l+1,m} \) with \( l \) differing by one unit.
An explicit calculation of the first-order modes in Cartesian coordinates, up to \( l = 3 \), is shown in Table II. For the expression of the modes in cylindrical coordinates, see Table IV in Appendix A. A similar parametrization has been proposed in the context of the SNS nEDM project [24,25]. See also [26] for the application of the scalar magnetic potential method in other precision experiments with polarized neutrons. In fact, the use of spherical harmonics to describe a near-uniform field appeared first in the context of nuclear magnetic resonance [27] and then in magnetic resonance imaging [28,29], where field uniformity is also of great importance.

When dealing with a perfectly uniform magnetic field, that field is described by the \( l = 0 \) terms only and we simply have

\[
G_{0,-1} = B_x, \quad (7)
\]

\[
G_{0,0} = B_z, \quad (8)
\]

\[
G_{0,1} = B_y. \quad (9)
\]

In the case of a field with uniform gradients, that field is described by the \( l = 0 \) and 1 terms and we have

\[
G_{1,-2} = \partial_z B_x = \partial_x B_y, \quad (10)
\]

\[
G_{1,-1} = \partial_z B_z = \partial_y B_x, \quad (11)
\]

\[
G_{1,0} = \partial_z B_y = -\partial_x B_z - \partial_y B_y, \quad (12)
\]

\[
G_{1,1} = \partial_x B_x = \partial_z B_y, \quad (13)
\]

\[
G_{1,2} = \frac{1}{2}(\partial_x B_x - \partial_y B_y). \quad (14)
\]
The harmonic polynomial expansion of the field nonuniformities given by Eq. (2) is a natural generalization of the description in terms of uniform gradients. The coefficients $G_{l,m}$ are the generalized gradients for the modes of degree $l$. Given the degree of maturity of nEDM experiments, this generalization is necessary to discuss the phenomena associated with field nonuniformity at the appropriate level of accuracy.

III. FIELD UNIFORMITY AND STATISTICAL PRECISION: NEUTRON DEPOLARIZATION

We now discuss the effects of a nonuniform magnetic field on the statistical uncertainty, which is limited by the precision of the determination of the neutron precession frequency $f_n$. The measurement of $f_n$ uses Ramsey’s method of separated oscillatory fields. In short, a chamber is first filled with polarized ultracold neutrons, and then a $\pi/2$ pulse is applied to the neutron spins using a transverse oscillating field. The neutron spins then precess in the transverse plane for a precession time $T$. Finally a second $\pi/2$ pulse is applied, and the chamber is then opened to count the number of spin-up and spin-down neutrons. The asymmetry in the counting depends on the difference between the applied frequency (used to generate the pulses) and the Larmor frequency $f_0$ (to be measured). With this method the statistical uncertainty on the neutron EDM due to Poisson fluctuations of the neutron counts is

$$\sigma d_n = \frac{\hbar}{2\alpha EN} \sqrt{N}$$

where $E$ is the electric-field strength, $N$ is the total number of neutrons measured during the measurement sequence, and $\alpha$ is the visibility—or contrast—of the Ramsey resonance, which refers to the polarization of the ultracold neutrons at the end of the precession period multiplied by the analyzing power of the spin analyzer system. In order to keep the visibility $\alpha$ as high as possible, all the depolarization mechanisms at play during the precession time must be understood and minimized. Typically, in the current experiment at PSI with a single chamber, we achieved $\alpha \approx 0.75$ after a precession time of $T = 180$ s.

In previous works [30–32], we have identified the main mechanisms responsible for the decay of the neutron polarization while they are stored in the chamber. The variation of $\alpha$ with respect to the precession duration can be written as a sum of three contributions:

$$\frac{d\alpha}{dT} = -\frac{\alpha}{T_{2,\text{wall}}} - \frac{\alpha}{T_{2,\text{mag}}} + \alpha_{\text{grav}},$$

where $T_{2,\text{wall}}$ is the transverse spin-relaxation time due to wall collisions (see Sec. III A), $T_{2,\text{mag}}$ is the transverse spin-relaxation time due to intrinsic depolarization in a nonuniform field (see Sec. III C), and $\alpha_{\text{grav}}$ is the contribution from gravitationally enhanced depolarization (see Sec. III B). Note that Eq. (16) applies to spins that are precessing in the magnetic field; this process is called transverse depolarization. The corresponding situation for when spins are aligned along the holding field is called longitudinal depolarization. In this case the depolarization rate $1/T_1$ also receives contributions from wall collisions and field nonuniformities as

$$\frac{1}{T_1} = \frac{1}{T_{1,\text{wall}}} + \frac{1}{T_{1,\text{mag}}},$$

and it is in general different from the transverse depolarization rate. We will now review all of these mechanisms in more detail.

A. Wall depolarization

When colliding with the wall of the precession chamber, a neutron can have its spin affected by magnetic impurities contained within the wall. Given that the interaction time with the wall is much shorter than the Larmor precession period, and that any orientation of the spin is equally affected on average, we can anticipate that the transverse and longitudinal relaxation rates will be identical:

$$\frac{1}{T_{2,\text{wall}}} = \frac{1}{T_{1,\text{wall}}} = \beta \nu,$$

where $\beta$ is the depolarization probability per wall collision and $\nu$ is the average frequency of wall collisions. Suitable materials have depolarization probabilities in the range $10^{-6} \leq \beta \leq 10^{-3}$ (see [33] for a recent work on wall depolarization). In practice the wall collision frequency is less than 50 s$^{-1}$, and $T_1$ is generally measured to be longer than 2000 s. Therefore, although wall depolarization is not a negligible process, it does not constitute a serious limitation for maintaining a high polarization.

B. Gravitationally enhanced depolarization

Ultracold neutrons are neutrons of extremely low kinetic energy, typically 200 neV or less. They are therefore significantly affected by gravity: different energy groups of neutrons have different mean heights in the chamber. In the presence of a vertical field gradient, the spins of neutrons in different energy groups precess at a slightly different rate, resulting in a phenomenon referred to as gravitationally enhanced depolarization. This mechanism concerns the transverse depolarization only.

For a quantitative description of the effect, we assume that the field can be described by the polynomial expansion up to order $l = 1$. We denote the probability for a neutron to belong to the energy group $e$ as $n(e)\, de$. After the precession time $T$, spins belonging to the energy group $e$ have accumulated a phase difference, with respect to the average phase of all neutrons, of

$$\psi(e, T) = \gamma_0 G_{1,0}(\bar{z}(e) - \langle z \rangle)T,$$

where $\bar{z}(e)$ is the mean height of neutrons in this group, $\langle z \rangle$ is the mean height of the whole ensemble of neutrons, and $\gamma_0$ is the neutron gyromagnetic ratio. Assuming that each group of neutrons is initially perfectly polarized, and neglecting the depolarization within a group, the final polarization after the precession time $T$ is

$$\alpha(T) = \int \cos \psi(e, T) n(e)\, de.$$
second-order Taylor expansion:

\[
\alpha(T) = -1 - \frac{1}{2} \int \varphi(\epsilon, T) n(\epsilon) d\epsilon.
\]

Finally, the depolarization rate \( \dot{\alpha}_{\text{grav}} \) is obtained from the derivative of the previous expression over precession time:

\[
\dot{\alpha}_{\text{grav}} = -\gamma_n^2 G^2_{1,0} \text{Var}[\bar{z}] T,
\]

with \( \text{Var}[\bar{z}] \) the variance of the distribution of \( \bar{z}(\epsilon) \):

\[
\text{Var}[\bar{z}] = \int (\bar{z}(\epsilon) - \bar{z})^2 n(\epsilon) d\epsilon.
\]

**C. Intrinsic depolarization**

The intrinsic depolarization refers to the decay of polarization within an energy group. It is due to the fact that different neutrons in a group have different random trajectories in a nonuniform field and therefore different histories of the magnetic field \( B(t) \). This process can be described by spin-relaxation theory, which is a general approach to calculate frequency shifts and relaxation rates on a quantum system in terms of the correlation function of the disturbance, to second order in the disturbance. In our case the disturbances are the field components \( B_i(t) \) with \( i \in \{x, y, z\} \), and their correlation functions \( \langle B_i(t_1)B_j(t_2) \rangle \) are the ensemble averages of the quantities \( B_i(t_1)B_j(t_2) \) over the neutrons stored in the chamber. Here we assume that the motion of the neutrons in the chamber is stationary in the statistical sense and therefore \( \langle B_i(t_1)B_j(t_2) \rangle = \langle B_i(0)B_j(t_2 - t_1) \rangle \). Specifically, it is the deviation from the mean value of the field components, \( B'_i(t) = B_i(t) - B_i \), that induces the relaxation of the spin. In the language of random processes, \( B'_i(t) \) is the centered variable associated with \( B_i(t) \), hence the notation with the exponent c.

Applying the spin-relaxation theory to our problem of spin-1/2 particles in a bottle [34–36], one finds

\[
\frac{1}{T_{1,\text{mag}}} = \gamma_n^2 \int_0^\infty \langle B'_x(0)B'_y(t) + B'_y(0)B'_z(t) \rangle \cos \omega t dt
\]

for the longitudinal relaxation rate and

\[
\frac{1}{T_{2,\text{mag}}} = \frac{1}{2T_{1,\text{mag}}} + \gamma_n^2 \int_0^\infty \langle [B'_x(0)B'_z(t)] \rangle dt
\]

for the transverse relaxation rate. In these expressions, \( \omega = \gamma_n B_0 \) is the angular Larmor precession frequency, and \( \langle X \rangle \) refers to the ensemble average of the quantity \( X \) over the neutrons stored in the chamber.

In fact, the depolarizations induced by the field components \( B_x \) and \( B_z \) transverse to the holding field \( B_0 \) are very small. In the regime where the precession frequency \( f_n \) is much higher than the wall collision frequency \( v \), it has been shown [31] that the order of magnitude of the longitudinal depolarization rate can be estimated by

\[
\frac{1}{T_{1,\text{mag}}} \sim \frac{v^3 \Delta B^2_{T}}{80 R^3 \gamma_n^2 B_0^2},
\]

where \( v \) is the neutron speed, \( R \) is the radius of the chamber (assumed to be cylindrical, with the axis aligned along \( z \)), and \( \Delta B_T \) is the typical value for the transverse field difference in the chamber. Note that a uniform transverse field has no effect.
(1) Longitudinal polarization: Neutrons are stored with their spin aligned with the holding magnetic field, and no spin-flip pulse is applied. During storage the polarization decreases at a rate given by Eq. (17).

(2) Ramsey: A $\pi/2$ pulse is applied at the beginning and at the end of the precession period (with a duration of 2 s each), so that the neutron spins precess in the holding field during the storage period. This is the normal mode of operation during nEDM runs because it allows a precise determination of the precession frequency. During precession the polarization decreases at the rate given by Eq. (16).

(3) Spin echo: In addition to the two $\pi/2$ pulses applied at the beginning and at the end of the precession period, a $\pi$ pulse is applied exactly halfway through the precession time. The effect of the $\pi$ pulse is to cancel the dephasing of different neutron energy groups [32], and therefore the depolarization rate is given by $d\alpha/dT = -\alpha/T_{w,\text{wall}} - \alpha/T_{w,\text{mag}}$. This mode allows one to isolate the intrinsic transverse depolarization from the gravitationally enhanced depolarization.

At the end of the storage period the ultracold neutrons are released from the precession chamber by opening the UCN shutter, allowing them to proceed to the spin analyzer [39]. This device simultaneously counts the neutrons in each of the spin states: it has two arms, each of which includes (i) an adiabatic spin flipper, (ii) a magnetized iron foil that transmits one spin component and reflects the other, and (iii) a set of $^6$Li-doped glass scintillators [40] to count the neutrons. Finally, the asymmetry

$$A = \frac{N_1 - N_2}{N_1 + N_2}$$

(30)
is calculated. The efficiency of the spin analyzer is not perfect due to the finite efficiency (about 90%) of the magnetized foils.

For measurements in the longitudinal and spin-echo modes, the polarization is directly given by the asymmetry, i.e., $\alpha = A$. In the Ramsey mode, the polarization is given by the asymmetry at the resonance, i.e., $\alpha = A(f_{\text{rad}} = f_{\text{rf}})$. In practice one measures the asymmetry as a function of the applied frequency $f_{\text{rf}}$ of the $\pi/2$ pulses for several (typically eight) cycles and then fits the Ramsey fringe by a cosine function. The polarization $\alpha$ is given by the maximum—or visibility—of the Ramsey curve $A$ versus $f_{\text{rf}}$.

The gradients $G_{1,0}$ or $G_{1,1}$ are applied by setting well-defined currents in the set of correcting coils. The gradients are measured in real time with an array of cesium magnetometers.

Figure 1 shows the results of a measurement of the final polarization as a function of an applied vertical gradient $G_{1,0}$. Within the range of applied gradients, $|G_{1,0}| < 50 \text{ pT/cm}$, the longitudinal polarization and the spin-echo polarization are constant. This is consistent with the expectation from Eq. (29) that the intrinsic magnetic depolarization is too small to be measured. The fact that the spin-echo polarization is smaller than the longitudinal polarization could be explained by possible residual horizontal gradients of the type $G_{1,1}$. We observe gravitationally enhanced depolarization in the Ramsey mode, with the polarization decreasing under the application of a finite gradient. We fit the model $\alpha(G_{1,0}) = \alpha_0 - \frac{\gamma}{2} \varv^2 G_{1,0}^2 \text{Var}[\tilde{\alpha}] T^2$ to the data with $\alpha_0$ and $\text{Var}[\tilde{\alpha}]$ as free parameters. We find $\text{Var}[\tilde{\alpha}] = 0.18 \pm 0.06 \text{ cm}^2$, a plausible value for stored ultracold neutrons.

Figure 2 shows the result of scanning the horizontal gradient $G_{1,1}$. The precession time was kept constant at $T = 180$ s. In this case, as expected, the applied gradient affects the polarization in the same manner as for the spin-echo and Ramsey runs. We have plotted (dashed line) the expected polarization after a spin-echo run; triangles, polarization after a normal Ramsey run. The dashed line is a fit of the gravitationally enhanced depolarization model based on Eq. (22) to the data (excluding the two points at large gradients for which the small phase approximation is not valid).

$$\alpha = A$$

\[ (30) \]
dependence
\[ \alpha(G_{1,1}) = \alpha_0 \exp \left( -\frac{T}{T_{2,\text{mag}}(G_{1,1})} \right), \]
(31)
where \( T_{2,\text{mag}}(G_{1,1}) \) is given by the intuitive model Eq. (29) and we have chosen the parameters \( \alpha_0 = 0.75 \) and \( v = 3 \text{ m/s} \).

Clearly, the data from the \( G_{1,0} \) and \( G_{1,1} \) scans are in good qualitative agreement with the expectations. There are two different mechanisms at play. The horizontal gradient \( G_{1,1} \) induces a truly irreversible depolarization process, since the polarization cannot be recovered by the spin-echo method. On the other hand, the vertical gradient \( G_{1,0} \) mainly affects the polarization through a loss of coherence of different energy groups separated by gravity; this coherence can be recovered through the spin-echo technique.

IV. FIELD UNIFORMITY AND SYSTEMATIC EFFECTS: FREQUENCY SHIFTS

In the present section we will cover the case of Larmor frequency shifts of particles—ultracold neutrons or atoms—evolving in a nonuniform magnetic field in conjunction with an electric field. We first review the linear-in-electric-field frequency shift, which constitutes an important direct systematic effect. In particular we calculate the false mercury EDM in terms of the coefficients of the expansion in the magnetic inversion, and we discuss the effects of higher-order modes. We will then review the electric-field-independent frequency shifts.

A. Motional false EDM

When a particle moves with a velocity \( v \) through a static electric field \( E \), it experiences a (relativistic) motional magnetic field \( B_m = E \times v / c^2 \). For trapped particles the velocity averages to zero, and therefore one is naively led to conclude that the effect vanishes. This is indeed the case if the magnetic field is perfectly uniform. However, when the particle spins in a nonuniform magnetic field the motional field \( B_m \) does induce a linear-in-electric-field frequency shift \( \delta f \). This effect has been extensively studied theoretically [36,41–49].

The associated false EDM can be calculated in the framework of spin-relaxation theory:
\[ d_{\text{false}} = -\frac{\hbar v_{\text{rms}}^2}{2c^2} \left( \frac{\partial B_m}{\partial x} \right) \cos \omega t \, dt. \]
(32)

Now, the magnitude of this undesirable false EDM critically depends on whether the particles are moving quickly or slowly, in a sense that we shall define. With a mean square velocity \( v_{\text{rms}} = \sqrt{\langle v_x^2 \rangle} \), it typically takes a time \( \tau_c = 2R / v_{\text{rms}} \) for a particle to diffuse from one side of the chamber to the other (\( 2R \) is the typical transverse size of the chamber, for example its diameter in the case of a cylindrical chamber). After this time a correlation function of the type \( \langle B_x(0)v_x(t) + B_y(0)v_y(t) \rangle \cos \omega t \, dt \) will have decayed to a small value. The adiabaticity parameter is defined as \( \alpha = \omega \tau_c \). For ultracold neutrons one usually has \( \alpha \tau_c \gg 1 \), which means that the Larmor frequency is much faster than the wall collision rate: This is the adiabatic regime of slow particles in a high field. On the other hand, for mercury atoms at room temperature in a \( B_0 = 1 \mu \text{T} \) field \( \omega \tau_c < 1 \); This is the nonadiabatic regime of fast particles in a low field. In the adiabatic regime, the linear-in-electric-field frequency shift can be interpreted as originating from a geometric phase, as first noticed in [50]. In fact the motional false EDM was called the geometric phase effect in earlier publications.

The general expression for the motional false EDM given in Eq. (32) takes simplified forms in the adiabatic and nonadiabatic approximations:
\[ d_{\text{false}} = -\frac{\hbar v_{\text{rms}}^2}{2c^2} \left( \frac{\partial B_m}{\partial x} \right) \cos \omega t \, dt \]
(33)
\[ d_{\text{false}} = -\frac{\hbar v_{\text{rms}}^2}{2c^2} \left( xB_x + yB_y \right) \]
(34)
where the brackets now refer to the volume average over the precession chamber. It should be emphasized that these expressions are valid for an arbitrary form of the magnetic nonuniformity.

In the simple case of a uniform gradient, i.e., \( G_{1,0} \neq 0 \) and all other \( G_{1,m} \) modes set to zero, in a cylindrical chamber of diameter \( 2R = 47 \text{ cm} \), these expressions can be simplified for the neutron (adiabatic case) and mercury (nonadiabatic case) false EDM [59]:
\[ d_{\text{false}} = -\frac{\hbar v_{\text{rms}}^2}{2c^2} G_{1,0} \]
(35)
\[ d_{\text{false}} = \frac{\hbar v_{\text{rms}}^2}{8c^2} R^2 G_{1,0} \]
(36)
\[ d_{\text{false}} = \frac{\hbar v_{\text{rms}}^2}{2c^2} \left( xB_x + yB_y \right) \]
(37)
\[ d_{\text{false}} = \frac{\hbar v_{\text{rms}}^2}{2c^2} \left( xB_x + yB_y \right) \]
(38)

the neutron case being calculated with \( v_{\text{rms}} = 2 \text{ m/s} \) and with \( B_0 = 1 \mu \text{T} \). Because the mercury comagnetometer is used to correct the neutron frequency for the drifts of the magnetic field, the false EDM of the mercury atoms translates to a false neutron EDM with a magnitude of
\[ d_{\text{false}} = \frac{\gamma_n}{\gamma_{Hg}} d_{\text{false}} \]
(39)
\[ d_{\text{false}} = \frac{\gamma_n}{\gamma_{Hg}} d_{\text{false}} \]
(40)

It should be noted that the mercury-induced false neutron EDM is much larger than the directly induced neutron motional false EDM.

In fact, it can be shown that the false EDM of a trapped particle is maximum at zero magnetic field, i.e., in the nonadiabatic limit. This explains why the mercury comagnetometer running at \( B_0 = 1 \mu \text{T} \) is a source of large systematic effects. It should be said that, despite the existence of such (by now well understood) effects, the use of a comagnetometer for well understood) effects, the use of a comagnetometer for other (2R is the typical transverse size of the chamber, for example its diameter in the case of a cylindrical chamber). After this time a correlation function of the type \( \langle B_x(0)v_x(t) + B_y(0)v_y(t) \rangle \cos \omega t \, dt \) will have decayed to a small value. The adiabaticity parameter is defined as \( \alpha = \omega \tau_c \). For ultracold neutrons one usually has \( \alpha \tau_c \gg 1 \), which means that the Larmor frequency is much faster than the wall collision rate: This is the adiabatic regime of slow particles in a high field. On the other hand, for mercury atoms at room temperature in a \( B_0 = 1 \mu \text{T} \) field \( \omega \tau_c < 1 \); This is the nonadiabatic regime of fast particles in a low field. In the adiabatic regime, the linear-in-electric-field frequency shift can be interpreted as originating from a geometric phase, as first noticed in [50]. In fact the motional false EDM was called the geometric phase effect in earlier publications.

The general expression for the motional false EDM given in Eq. (32) takes simplified forms in the adiabatic and nonadiabatic approximations:
\[ d_{\text{false}} = -\frac{\hbar v_{\text{rms}}^2}{2c^2} \left( \frac{\partial B_m}{\partial x} \right) \cos \omega t \, dt \]
(33)
\[ d_{\text{false}} = -\frac{\hbar v_{\text{rms}}^2}{2c^2} \left( xB_x + yB_y \right) \]
(34)
where the brackets now refer to the volume average over the precession chamber. It should be emphasized that these expressions are valid for an arbitrary form of the magnetic nonuniformity.

In the simple case of a uniform gradient, i.e., \( G_{1,0} \neq 0 \) and all other \( G_{1,m} \) modes set to zero, in a cylindrical chamber of diameter \( 2R = 47 \text{ cm} \), these expressions can be simplified for the neutron (adiabatic case) and mercury (nonadiabatic case) false EDM [59]:
\[ d_{\text{false}} = -\frac{\hbar v_{\text{rms}}^2}{2c^2} G_{1,0} \]
(35)
\[ d_{\text{false}} = \frac{\hbar v_{\text{rms}}^2}{8c^2} R^2 G_{1,0} \]
(36)
\[ d_{\text{false}} = \frac{\hbar v_{\text{rms}}^2}{2c^2} \left( xB_x + yB_y \right) \]
(37)
\[ d_{\text{false}} = \frac{\hbar v_{\text{rms}}^2}{2c^2} \left( xB_x + yB_y \right) \]
(38)

bath, for which the false EDM can be set to zero by adjusting the temperature of the bath [43]. At room temperature, though, another alternative that has recently been proposed by one of us is to operate the mercury comagnetometer at a higher “magic” magnetic field to set the false EDM to zero [51]. While this is an attractive possibility for a future experiment, it brings with it significant difficulties in ensuring the uniformity of the magnetic field to the level required to avoid depolarization of the neutrons. In the remainder of the present paper we will consider the nonadiabatic regime for the mercury comagnetometer.

The mercury false EDM value given by Eq. (38) is in practice times larger than the $d_{\text{Hg}}$ experimental upper bound from direct searches for the Hg atomic EDM, $d_{\text{Hg}} < 7.4 \times 10^{-34} e cm$ [52], where the presence of a 0.5-bar buffer gas reduces the size of the motional false EDM to $d_{\text{Hg}} < 7 \times 10^{-34} e cm$ [52,53] in this experiment.

We will now give expressions for the mercury-induced false EDM in the case of more general magnetic nonuniformities described by the harmonic polynomial expansion (2). From Eqs. (34) and (39) we find

$$d_{\text{Hg}} = -\frac{\hbar |\gamma_0| |\gamma_1|}{2c^2} \sum_{l,m} G_{l,m}(\rho \Pi_{l,m}), \quad (41)$$

where $\rho, z, \phi$ are the cylindrical coordinates and

$$\Pi_{l,m,=0} = \cos \phi \Pi_{x,l,m} + \sin \phi \Pi_{y,l,m} = \partial_\phi \Sigma_{l+1,m} \quad (42)$$

is the radial component of the mode $l, m$. In Table III we give expressions for the radial components of the first $m = 0$ modes (see Appendix A for more information on the harmonic polynomials in cylindrical coordinates).

Next, we specify the formula (41) in the case of a cylindrical chamber of radius $R$ and height $H$. The origin of the coordinate system is at the center of the cylinder. All $m \neq 0$ modes satisfy $(\rho \Pi_{l,m}) = 0$ due to the average over $\phi$. All even $l$ modes satisfy $(\rho \Pi_{l,0}) = 0$ due to the average over $z$. Therefore, only the modes $\Pi_{l,0}$ with $l$ odd contribute to the mercury-induced false EDM:

$$d_{\text{Hg}} = -\frac{\hbar |\gamma_0| |\gamma_1|}{2c^2} \sum_{l \text{ odd}} G_{l,0}(\rho \Pi_{l,0}) \quad (43)$$

$$= \frac{\hbar |\gamma_0| |\gamma_1|}{8c^2} \left[ G_{1,0} - G_{3,0} \left( \frac{R^2}{2} - \frac{H^2}{4} \right) \right]$$

$$+ G_{3,0} \left( \frac{5R^4}{16} - \frac{5R^2H^2}{12} + \frac{H^4}{16} \right) + \cdots \right]. \quad (44)$$

The motional false EDM of mercury induced by the linear gradient $G_{1,0}$ has been experimentally confirmed in [54], by applying an artificially large gradient. More recently we have also verified the effect induced by the cubic term $G_{3,0}$ with a dedicated measurement as reported in Sec. IV B. The motional false EDM is a dominant systematic effect that must be compensated for, and in order to determine the true EDM from experimental values one must extrapolate the measured EDM to zero gradient. An effective strategy for that extrapolation, used in the previous measurement [14], takes advantage of neutron frequency shifts which are also sensitive to the gradients. We will review these frequency shifts in Sec. IV C and explain the correction strategy using the gravitational shift in Sec. IV E.

### B. Experimental verification of the false EDM induced by the cubic mode

In order to verify the accuracy of the predicted false EDM $d_{\text{false}}$, a dedicated measurement was performed in the neutron EDM experiment at PSI using different magnetic-field gradients. In a previous work [54] we verified that a linear gradient $G_{1,0}$ produces a motional false EDM on the mercury as predicted by the theory. Here we extend this verification to the false EDM produced by the cubic mode $G_{3,0}$.

In this measurement no neutrons were used, and the $^{199}\text{Hg}$ precession frequency $f_{\text{Hg}}$ was monitored while the applied electric field was periodically reversed: $E = \pm 120 \text{ kV/cm}$. The measurements were performed in a series of standard cycles for which the sequence begins with the filling of the precession chamber with spin-polarized Hg atoms. The Hg spin is then flipped to a transverse direction (with respect to $B_0$) using a $\pi/2$ magnetic resonance pulse of 2-s duration. A weak circularly polarized light beam is used to monitor the precessing transverse Hg spins by measuring the light power transmitted through the Hg medium. Due to the spin-dependent part of the absorption coefficient, the transmitted power is modulated synchronously with the spin precession. After recording the free-spin precession for 72 s, the cycle ends with the emptying of the precession chamber. Cycles were repeated every 100 s, and the $E$ field was reversed in a $+\rightarrow -\rightarrow +$ pattern where every entry in the pattern consists of ten cycles.

The change in Hg precession frequency $\Delta f_{\text{Hg}}$ correlated with the change in electric field $\Delta E$ was analyzed by averaging over many electric-field changes. The pattern $+\rightarrow -\rightarrow +$ suppresses the effect of linear drifts in the Hg precession frequency due to slow changes of the magnetic field in the apparatus. Periods during which the magnetic field changed rapidly (e.g., because of ramping superconducting magnets in neighboring experiments) were cut from the data analysis.

We took data in a number of different magnetic-field configurations. To change the cubic mode $G_{3,0}$ we applied appropriate currents in trim coils mounted around the precession volume. For each magnetic-field configuration we calculate the false EDM as

$$d_{\text{false}} = \frac{\pi \hbar}{2|E|} (f_{\text{Hg},+\uparrow} - f_{\text{Hg},-\uparrow}). \quad (45)$$
We selected pairs of runs that only differ by the value of the cubic mode. We report in Fig. 3 the difference $\Delta d^{\text{false}}$ between each pair as a function of the cubic mode difference $G_{3,0}$. The value $G_{3,0}$ is inferred by analyzing field maps. We plan to describe the field mapping device and the analysis of the recorded maps in a later publication.

Figure 3 also shows the theoretical expectation

$$\Delta d^{\text{false}} = \frac{\hbar \gamma_n^2}{8 c^2} R^2 \left( \frac{R^2}{2} - \frac{H^2}{4} \right) G_{3,0}. \tag{46}$$

The measurement is in good agreement with the theory. More details about this measurement can be found in the Ph.D. thesis of Komposch \cite{55}.

C. Electric-field-independent frequency shifts

We will now discuss the frequency shifts unrelated to the electric field in situations where the Larmor frequencies of the neutrons $f_n$ and mercury atoms $f_{Hg}$ are measured in a weak magnetic field $B_0 = 1 \mu$T.

There are several known effects that could significantly shift the ratio $\mathcal{R} = f_n / f_{Hg}$ from its unperturbed value $[\gamma_n / \gamma_{Hg}]$. For the purpose of the present discussion we write the combination of these effects as

$$\mathcal{R} = \frac{f_n}{f_{Hg}} = \left| \frac{\gamma_n}{\gamma_{Hg}} \right| \left( 1 + \delta_{\text{Grav}} + \delta_T + \delta_{\text{other}} \right). \tag{47}$$

The term $\delta_{\text{Grav}}$ is called the gravitational shift and $\delta_T$ is the shift due to transverse magnetic fields. The last term, $\delta_{\text{other}}$, accounts for shifts unrelated to the field uniformity. It includes the effect of Earth rotation \cite{56}, Ramsey-Bloch-Siegert shifts due to imperfect $\pi/2$ pulses, and light shifts induced by the UV light probing the mercury precession. A discussion of these effects, which in practice are subdominant, is beyond the scope of this paper; they were briefly discussed in \cite{57}. The first two terms $\delta_{\text{Grav}}$ and $\delta_T$ are of interest here because they are induced by the magnetic-field nonuniformity.

The gravitational shift $\delta_{\text{Grav}}$ is the dominating shift in Eq. (47). As we already have mentioned when discussing gravitational depolarization, ultracold neutrons “sag” towards the bottom of the chamber quite significantly due to gravity. In contrast, the mercury atoms form a gas at room temperature that fills the precession chamber uniformly. This results in slightly different average magnetic fields for the neutrons and the atoms in the presence of a vertical field gradient. In the framework of the harmonic expansion of the field, the volume average of the vertical component is

$$\langle B_z \rangle = \sum_{l,m} G_{l,m} (\Pi_{z,l,m}). \tag{48}$$

For both mercury atoms and neutrons we have

$$\langle \rho^2 \rangle = \frac{R^2}{2}. \tag{50}$$

For the mercury atoms we have

$$\langle z^2 \rangle_{Hg} = 0, \tag{51}$$
$$\langle \rho^2 \rangle_{Hg} = \frac{H^2}{12}, \tag{52}$$
$$\langle z^3 \rangle_{Hg} = 0. \tag{53}$$

Therefore, the averaged field, which we call the $B_0$ field, is

$$B_0 := \langle B_z \rangle_{Hg} = G_{0,0} + G_{2,0} \left( \frac{H^2}{12} - \frac{R^2}{4} \right). \tag{54}$$

Now, for neutrons, the main difference when compared to atoms is that the center of mass $\langle z \rangle$,—which we denote simply as $\langle z \rangle$—is significantly nonzero and negative. To calculate the ensemble average of higher powers of $z$, we approximate the neutron density $n(z)$ to be a linear function of $z$. We find

$$\langle z^2 \rangle_n \approx \frac{H^2}{12}, \tag{55}$$
$$\langle z^3 \rangle_n \approx \frac{3H^2}{20}(z). \tag{56}$$

In reality the neutron density is not precisely a linear function of $z$. However, these expressions have been numerically verified to be accurate to better than a few percent for typical UCN spectra in storage vessels similar to those used. Therefore, the expression of the field averaged by the neutrons is

$$\langle B_z \rangle_n = G_{0,0} + G_{1,0}(z) + G_{2,0} \left( \frac{H^2}{12} - \frac{R^2}{4} \right) + G_{3,0} \left( \frac{3H^2}{20} - \frac{3R^2}{4} \right)(z). \tag{57}$$
From Eqs. (54) and (57) we deduce the gravitational shift
\[ \delta_{\text{grav}} = \frac{\langle B \rangle_n}{\langle B \rangle_{\text{Hg}}} - 1 = \pm \frac{G_{\text{grav}}(z)}{|B_0|}, \] (58)
where the ± sign refers to the direction of the magnetic field and the term \( G_{\text{grav}} \) is given by the following combination:
\[ G_{\text{grav}} = G_{1,0} + G_{3,0} \left( \frac{3H^2}{20} - \frac{3R^2}{4} \right). \] (59)

The second shift in Eq. (47), \( \delta_T \), arises from residual transverse field components \( B_T \). As mentioned above, the neutrons fall into the adiabatic regime of slow particles in a high field, and therefore the spins precess at a rate given by the volume average of the modulus of the field:
\[ f_n = \frac{|\gamma_n|}{2\pi} \left( \langle |B| \rangle_n + \frac{\langle B_Z^2 \rangle}{2|B_0|} \right). \] (60)

The mercury atoms on the other hand fall into the nonadiabatic regime of fast particles in a low field, as a result of which the spins precess at a rate given by the vectorial volume average of the field:
\[ f_{\text{Hg}} = \frac{|\gamma_{\text{Hg}}|}{2\pi} |\langle B \rangle_{\text{Hg}}| = \frac{|\gamma_{\text{Hg}}|}{2\pi} |B_0|. \] (61)

Due to the fact that \( \langle B \rangle_n \neq B_0 \) is already accounted for by the gravitational shift, the expression for the transverse shift is simply
\[ \delta_T = \frac{\langle B_Z^2 \rangle}{2B_0^2}. \] (62)

The expression for \( \langle B_Z^2 \rangle \) in terms of the coefficients \( G_{1,n} \) is given in Appendix B.

D. Experimental verification of the gravitational and transverse shifts

In Fig. 4 we show a measurement of the ratio \( R = \frac{f_n}{f_{\text{Hg}}} \) as a function of an applied vertical field gradient \( G_{1,0} \). The underlying data are the same as those used to produce Fig. 1.
We observe that the dependence of \( R \) versus the gradient is not quite linear. Fitting only the linear part we find \( \langle z \rangle = -0.36(3) \text{ cm} \). The nonlinear behavior is primarily due to the phenomenon of Ramsey wrapping [30,31].

Next we report on a dedicated experiment to verify the frequency shift due to a transverse field. The measurements were performed at PSI in October 2017. We varied the transverse field component using a combination of trim coils optimized to induce only the \( G_{1,2} \) mode. Since the \( G_{1,2} \) mode is purely transverse, the scalar Cs magnetometers could not be used to measure it; instead we used offline fluxgate maps of the trim coils to determine the value of \( G_{1,2} \) as a function of the currents in the coils. Figure 5 shows the \( R \) ratio as a function of \( G_{1,2} \). We also carried out a similar test for the \( G_{1,-2} \) mode.

FIG. 4. Experimental verification of the gravitational shift: neutron-to-mercury frequency ratio \( R \) as a function of an applied vertical gradient \( G_{1,0} \). A linear fit to the data is performed (excluding the two points at large gradients) to extract \( \langle z \rangle \).

FIG. 5. Experimental verification of the transverse-gradient shift: neutron-to-mercury frequency ratio \( R \) as a function of applied transverse gradient \( G_{1,2} \). The dashed line is a symmetric parabola with the constant term fitted to the data and the quadratic term fixed to the theoretical value.
and that measurement is also in good agreement with the 
expected shift.

E. Correction strategy using the gravitational shift

We now suggest a strategy to correct for the motionless false 
EDM through use of the gravitational shift. We extend the 
method used in [14], which neglected possible \( l > 1 \) terms 
for the nonuniformity. Here we assume that the magnetic field 
can be described by the harmonic expansion up to \( l = 4 \) and 
we neglect for the time being all terms \( l > 4 \).

For a given sequence of measurements with a fixed 
magnetomagnetic-field configuration, the measured EDM is the sum 
of the true EDM and the false EDM, which can be written as

\[
d_n^{\text{meas}} = d_n^{\text{true}} + \frac{\hbar |\gamma_n| h|g|}{8c^2} \left[ G_{\text{grav}} + G_{3,0} \left( \frac{R^2}{4} + \frac{H^2}{10} \right) \right].
\]

(63)

On the other hand, the \( R \) ratio measured for that magnetic-field 
configuration is given by

\[
R = \left| \frac{\gamma_n}{\gamma_{Hg}} \right| \left( 1 + \frac{G_{\text{grav}}(z)}{|B_0|} + \delta_T + \delta_{\text{other}} \right).
\]

(64)

where the \((+)(-)\) sign refers to \( B_0 \) pointing upwards 
(downwards). We define the corrected quantities \( d_n^{\text{corr}} \) and 
\( R^{\text{corr}} \) to be

\[
d_n^{\text{corr}} = d_n^{\text{meas}} + \frac{\hbar |\gamma_n| h|g|}{8c^2} G_{3,0} \left( \frac{R^2}{4} + \frac{H^2}{10} \right)
\]

and

\[
R^{\text{corr}} = R / (1 + \delta_T + \delta_{\text{other}}).
\]

To calculate these, the magnetic-field related quantities \( G_{3,0} \) 
and \( |B_0| \) are required. They can be measured offline by 
field mapping, if the reproducibility of the magnetic-field 
configuration is sufficient.

Then, we have

\[
d_n^{\text{corr}} = d_n^{\text{true}} + \frac{\hbar |\gamma_n| h|g|}{8c^2} G_{\text{grav}}
\]

and

\[
R^{\text{corr}} = \left| \frac{\gamma_n}{\gamma_{Hg}} \right| \left( 1 + \frac{G_{\text{grav}}(z)}{|B_0|} \right).
\]

(65)

(66)

Therefore,

\[
d_n^{\text{corr}} = d_n^{\text{true}} + B_0 \frac{\hbar |\gamma_n| h|g|}{8c^2} \left( R^{\text{corr}} - \left| \frac{\gamma_n}{\gamma_{Hg}} \right| \right).
\]

(67)

(68)

(69)

Now, we have a set of kings (\( d_{\text{corr}}, R^{\text{corr}} \)), where each point 
corresponds to a different field configuration. It is important 
to get a set of points for both polarities of \( B_0 \). The so-called 
crossing-point analysis simply consists of fitting these 
two series of points with two linear functions with opposite 
slope. It gives direct access to \( d^{\text{true}} \), since at the crossing point

\[
d_n = d_n^{\text{true}} \text{ and } R^{\text{corr}} = \left| \frac{\gamma_n}{\gamma_{Hg}} \right|.
\]

This technique was extended in [14] to include the nonlinearity arising from Ramsey wrapping, resulting in a far more satisfactory fit to the data.

Let us now make a few remarks.

(1) In principle, one could extract \( G_{\text{grav}} \) from offline field 
mapping or with real-time magnetometers around the precession 
chamber, and correct the false EDM on a point-by-point 
basis without using the crossing-point analysis. However, this 
requires an accuracy better than 1 pT/cm for \( G_{\text{grav}} \) (corresponding 
to an error of 4.4 \( \times 10^{-7} \) cm), which is beyond the 
reach of the current experimental setup. The accuracy of the 
determination of the gradients will be discussed quantitatively 
in the two aforementioned forthcoming papers.

(2) An experiment with a vertical stack of two chambers, 
rather than just one, could simply measure the gradient by 
taking the field difference between the top and bottom chambers. This would be an alternative to the gradient extracted via the 
gravitational shift.

(3) The crossing-point condition \( R^{\text{corr}} = |\gamma_n/\gamma_{Hg}| \) allows an 
important cross-check of the analysis: \( R^{\text{corr}} \) should agree 
with \( |\gamma_n/\gamma_{Hg}| \) calculated from independent measurements of \( \gamma_n \) 
and \( \gamma_{Hg} \).

F. The special case of a localized magnetic dipole

The correction strategy presented in the previous paragraph 
compensates for the false EDM produced by a nonuniform 
field for all modes up to \( l = 4 \). However, it does not perfectly 
compensate for the systematic effect generated by a localized 
magnetic dipole situated close to the precession chamber, as 
pointed out in [58]. Indeed, the residual false EDM, after 
the correction procedure, is given by

\[
d_n^{\text{res}} = -\frac{\hbar |\gamma_n| h|g|}{2c^2} \left( xB_1^{\text{dip}} + yB_2^{\text{dip}} + zB_3^{\text{dip}} \right).
\]

(70)

where \( (B_1^{\text{dip}}, B_2^{\text{dip}}, B_3^{\text{dip}}) \) is the magnetic field generated by the 
local dipole. The first term corresponds to the systematic effect induced by the horizontal components of the dipole, and 
the second term arises from the correction procedure.

When the dipole is situated on the axis below or above the 
cyindrical chamber, an analytical expression for Eq. (70) 
can be derived [45]. In general, however, for an arbitrary position 
of the magnetic dipole, Eq. (70) has to be calculated numerically. Most critical are dipoles located on the circumference 
of the chamber.

We show in Fig. 6 a numerical calculation of the false 
EDM generated by a dipole oriented along \( z \), with a magnetic 
moment \( m_1 = 10 \text{nAm}^2 \). This dipole corresponds to a speck 
of spherical iron dust with diameter 20 \( \mu \text{m} \) magnetized to 
saturation.

V. SUMMARY AND DISCUSSION

In this paper we have discussed how magnetic-field 
nonuniformities affect the statistical and systematic errors in 
the measurement of the neutron electric dipole moment.

Concerning the statistical precision, the field uniformity 
must be sufficient to prevent the depolarization of ultracold 
neutrons during the precession time, which is as long as 
a few minutes. We have reviewed the main mechanisms 
of magnetic—gravitational and intrinsic—depolarization. We 
have reported upon dedicated measurements of these effects, 
in particular using the UCN spin-echo technique to separate 
the intrinsic and gravitationally enhanced depolarization 
components.
FIG. 6. Absolute residual false EDM created by a dipole located in the vertical plane $y = 0$, with a magnetic moment aligned with $z$ and with $m_z = 10$ nA m$^2$, as a function of the position $(x, z)$ of the dipole. The white area corresponds to the volume of the chamber (diameter 47 cm and height 12 cm).

As far as systematic effects are concerned, we have focused the discussion on those related to the mercury comagnetometer. In the previous literature, discussion about the false EDM effect in mercury was limited to linear gradients, although the case of localized dipoles was treated in [44,45,58]. In this paper we have extended the discussion to higher-order gradients. The theory for the motional false EDM is given in terms of a harmonic expansion. We have performed a dedicated measurement to verify the effect of the cubic mode in this expansion.

We have in preparation two companion papers on the subject of magnetic-field uniformity in the PSI nEDM experiment. The second part of this will present the procedure to produce a uniform field in situ with the help of an array of cesium magnetometers. The third part will present the offline characterization of the field uniformity through use of an automated mapping device.

ACKNOWLEDGMENTS

The experimental data were taken at PSI Villigen. In addition we are grateful for access granted to the computing grid infrastructure PL-Grid.

APPENDIX A: HARMONIC POLYNOMIALS IN CYLINDRICAL COORDINATES

It is useful to derive the expressions of the harmonic modes in cylindrical coordinates $(\rho, \phi, z)$ with $x = \rho \cos \phi$ and $y = \rho \sin \phi$. The radial, azimuthal, and vertical components, respectively, of the mode $l, m$ are given by

$$\Pi_{\rho,l,m} = \cos \phi \Pi_{x,l,m} + \sin \phi \Pi_{y,l,m}$$

(A1)

$$= \partial_\rho \Sigma_{l+1,m}$$

(A2)

$$\Pi_{\phi,l,m} = -\sin \phi \Pi_{x,l,m} + \cos \phi \Pi_{y,l,m}$$

(A3)

$$= \frac{1}{\rho} \partial_\phi \Sigma_{l+1,m}$$

(A4)

$$\Pi_{z,l,m} = \partial_z \Sigma_{l+1,m}$$

(A5)

It is possible to write a simplified expression for the vertical component. Starting from Eq. (4), we have

$$\Pi_{z,l,m} = C_{l+1,m}(\phi) \partial_\phi [\rho^{l+1} p_{l+1}^m(\phi)]$$

$$= C_{l+1,m}(\phi) \rho (l + 1) \rho p_{l+1}^m(\rho) + (1 - c^2) \partial_\rho p_{l+1}^m(\rho),$$

(A6)

where $c = \cos \theta$. Using the known property of the associated Legendre polynomials,

$$(c^2 - 1) \partial_\rho p_{l+1}^m(\rho) = (l + 1) c p_{l+1}^m(\rho) - (l + 1 + m) p_{l+1}^m(\rho),$$

(A7)

we arrive at

$$\Pi_{z,l,m} = C_{l+1,m}(\phi) (l + m + 1) \rho p_{l+1}^m(\cos \theta).$$

(A8)

It is also possible to write a simplified expression for the radial component, but only for the $m = 0$ modes. In that case,

$$\Pi_{\rho,l,0} = \frac{1}{l + 1} \partial_\rho [\rho^{l+1} p_{l+1}^0(\rho)]$$

$$= \frac{l}{l + 1} \sin \theta (l + 1) p_{l+1}^0(\rho) - c \partial_\rho p_{l+1}^0(\rho).$$

(A9)

We use the following property of the Legendre polynomials,

$$(l + 1) p_{l+1}^0(\rho) - c \partial_\rho p_{l+1}^0(\rho) = -\partial_\rho p_{l}^0(\rho),$$

(A10)

to find

$$\Pi_{\rho,l,0} = \frac{1}{l + 1} \frac{d}{d \theta} p_{l}^0(\cos \theta).$$

(A11)

An explicit calculation of the modes in cylindrical coordinates up to $l = 3$ is shown in Table IV.
APPENDIX B: TRANSVERSE FIELD COMPONENTS

In this Appendix we give the expression for the mean squared transverse field,

$$\langle B_T^2 \rangle_\text{LO} = \langle (B_x - B_z) \rangle^2 + \langle (B_y - B_z) \rangle^2, \quad (B1)$$

in terms of the generalized gradients $G_{l,m}$ up to order $l = 3$ for a cylindrical precession chamber of radius $R$ and height $H$.

It can be expressed as a sum of four contributions:

$$\langle B_T^2 \rangle = \langle B_T^2 \rangle_\text{LO} + \langle B_T^2 \rangle_\text{LO} + \langle B_T^2 \rangle_\text{LO} + \langle B_T^2 \rangle_\text{LO}. \quad (B2)$$

The linear-order contribution is

$$\langle B_T^2 \rangle_\text{LO} = R^2 \left( G_{1,-1}^2 + G_{1,1}^2 + \frac{1}{4} G_{1,0}^2 \right) + H^2 \left( G_{1,-1}^2 + G_{1,1}^2 \right). \quad (B3)$$

The quadratic-order contribution is

$$\langle B_T^2 \rangle_\text{LO} = \frac{R^4}{3} \left( G_{2,-3}^2 + G_{2,3}^2 \right) + \frac{R^4 H^2}{12} \left( 2G_{2,-2}^2 + 2G_{2,2}^2 + \frac{1}{2} G_{2,0}^2 \right) + \left( R^4 \frac{H^4}{24} + H^4 \frac{180}{180} \right) \left( G_{2,-1}^2 + G_{2,1}^2 \right). \quad (B4)$$

The cubic-order contribution is

$$\langle B_T^2 \rangle_\text{LO} = \frac{R^6}{4} \left( G_{3,-4}^2 + G_{3,4}^2 \right) + \frac{R^4 H^2}{4} \left( G_{3,-3}^2 + G_{3,3}^2 \right) + \frac{5R^6}{32} - \frac{9R^6 H^4}{160} \left( G_{3,-2}^2 + G_{3,2}^2 \right) + \frac{5R^6 H^2}{64} - \frac{3R^6 H^4}{160} + \frac{H^6}{448} \left( G_{3,-1}^2 + G_{3,1}^2 \right) + \frac{9R^6}{256} - \frac{R^6 H^4}{32} + \frac{9R^6 H^2}{640} \left( G_{3,0}^2 \right). \quad (B5)$$

Finally, there is the interference term between the linear and cubic modes:

$$\langle B_T^2 \rangle_\text{LO} = \left( -\frac{R^4}{2} + \frac{R^2 H^2}{4} \right) \left( G_{1,-2} G_{3,-2} + G_{1,2} G_{3,2} + \frac{1}{4} G_{1,0} G_{3,0} \right) + \left( -\frac{R^4 H^2}{8} + \frac{H^4}{40} \right) \left( G_{1,-1} G_{3,-1} + G_{1,1} G_{3,1} \right). \quad (B6)$$

Note that the quadratic modes do not interfere with the linear and cubic modes.

[59] We note a numerical error in the corresponding expression of Eq. (5) in [54].
