What diagnostic strategies can help differentiate cellulitis from other causes of red legs in primary care?

George Edwards research assistant¹, Karoline Freeman research fellow², Martin J Llewelyn professor³, Gail Hayward associate professor¹¹

¹Nuffield Department of Primary Care Health Sciences, Radcliffe Observatory Quarter, Oxford, UK; ²Warwick Medical School, Division of Health Sciences, University of Warwick, Coventry, UK; ³Brighton and Sussex Medical School, University of Sussex, UK

What you need to know

- Red legs owing to non-infectious causes are often misdiagnosed as cellulitis, resulting in unnecessary antibiotics and hospitalisation
- Novel approaches such as thermal imaging, clinical prediction models, point-of-care tests, and a visually based computerised diagnostic decision support system could potentially aid the diagnosis of cellulitis, but there is very limited and weak evidence to support their use in primary care
- Clinically, a unilateral presentation increases the odds of cellulitis, and lack of elevated temperature compared with the unaffected limb can help rule out cellulitis

Cellulitis is the most common bacterial infection causing red legs. It is treated with antibiotics, and patients with severe disease may need to be hospitalised.¹² In 2017-18, 317 522 patients were given a diagnosis of cellulitis in UK hospitals.¹³ The true incidence, including patients managed through primary care, is likely to be higher.

Redness is often accompanied by other classic signs of inflammation: tenderness, warmth, and swelling. Other causes of red legs can present with some, or all, of these common symptoms⁴ (table 1). These conditions may be misdiagnosed as cellulitis. Studies in US emergency departments have reported that between 28% and 30.7% of cellulitis diagnoses are incorrect. Misdiagnosis can result in unnecessary antibiotic treatment⁵ and hospitalisation. Conversely, untreated cellulitis can have complications such as extensive tissue damage and necrosis, disseminated infection, septic shock, and potentially death.⁶ Figures 1 and 2 show alternative diagnoses for red legs.

Differentiating red legs with bacterial causes from those with non-infectious causes presents a diagnostic dilemma in primary care. A systematic review published in 2019 highlighted the lack of validated diagnostic aids for lower limb cellulitis.¹⁰ In this review we also included studies of patients with cellulitis of any site on the body, and additionally searched conference abstracts. We excluded any technology or test that was unsuitable for use in primary care.

What is the evidence of uncertainty?

Search strategy and study selection

We searched Medline, Embase, and Web of Science from inception to July 2019 using terms for Skin or soft tissue infection including: cellulitis (MeSH term) OR bacterial skin disease OR soft tissue infections OR wound infections OR skin diseases OR bacterial OR erysipelas AND Diagnosis of skin infections including: diagnose* OR detect* OR screen* OR test*

Devices to aid differentiation of infectious from non-infection cases including: point of care testing, skin AND thermometers OR thermography, skin temperature, telethermogra*, bio* OR chem* OR electrochem* sensor OR sensors OR probe

We included studies of patients with skin or soft tissue infections, including cellulitis, erysipelas, and necrotising fasciitis. We included studies if they reported on the detection of skin infections, or investigated the differential of infectious and non-infectious skin

Studies of other infections, management strategies, prognosis, or severity were excluded, as were studies of technologies that were unsuitable for primary care

To find ongoing research we searched UK (ISRCTN), EU (clinicaltrialregister.eu), and US (clinicaltrials.gov) trial registries for trials concerning diagnosis of cellulitis, and additional searches for trials concerning diagnosis of erysipelas, bacterial skin disease, skin infections, and skin inflammation

We found eight small observational studies investigating four different diagnostic strategies for cellulitis that are non-invasive and potentially viable in primary care (box 1). Table 2 describes the findings of these studies. There is insufficient evidence to recommend implementation of any of these strategies in primary care. Seven of eight studies recruited patients from emergency departments, who may have had more severe symptoms than those presenting to primary care. All studies used highly selective populations, including only patients who were suspected to have cellulitis by an emergency department clinician or dermatologist and excluding patients with other
relevant diagnoses such as soft tissue abscess, osteomyelitis, and diabetic ulcers. In an undifferentiated primary care population test performance may be poorer.

**Box 1: Possible diagnostic aids to detect cellulitis in primary care**

**Thermal imaging**
Thermal imaging compares the temperature of an area of suspected cellulitis with a contralateral site on the body. Thermal cameras are available as smartphone attachments

**Clinical prediction models**

**ALT 70**
Using final discharge diagnosis of cellulitis as a reference standard, four features were found to be predictive of “true” cellulitis: Asymmetry (3 points), Leucocytosis (1 point), Tachycardia (1 point), and age ≥70 (2 points).

Unilateral leg involvement was associated with an adjusted odds ratio of 8.65 for cellulitis, the highest of the four variables in the score.

**NEWHAuN score system**
New onset, Erythema, Warmth/fever, History of trauma, Ache, Unilaterality and Number of white cells

**Visually based computerised diagnostic decision support system (VCDDSS)**
The VCDDSS suggests alternative diagnoses in the form of peer reviewed photographs or diagrams of medical conditions from the most to the least likely, based on symptoms input by the clinician

**Procalcitonin**
Procalcitonin is an inflammatory response protein which can be measured at the point of care. Procalcitonin levels greater than 0.25 mcg/L are associated with some bacterial infections.

The quality of all studies, assessed using the QUADAS-2 framework (recommended tool to evaluate the risk of bias and applicability of primary diagnostic accuracy studies) was poor. In five studies it was unclear whether the researchers using the novel tests were blind to the confirmed diagnosis. Prolonged time intervals between the test of interest and confirmation of disease in most studies and the use of different methods to confirm diagnosis (in two studies) may have biased the results.

Cellulitis is largely a clinical diagnosis and the lack of a diagnostic reference standard poses a key challenge to assessing the performance of diagnostic tests. Most studies rely on diagnosis of cellulitis by a dermatologist as a proxy diagnostic approach to evaluating the performance of diagnostic tests. Most studies rely on cellulitis as a reference standard.

Several conditions can cause red legs. One of these is a bacterial infection called cellulitis.

**Is ongoing research likely to provide relevant evidence?**

We searched UK, EU, and US registries for ongoing studies and found two of potential relevance. The first, a prospective cohort study, aims to evaluate the accuracy of non-contact infrared measurement of skin temperature to distinguish limb cellulitis from pseudo cellulitis in 50 adults. The second, a before-and-after study, aims to evaluate point-of-care ultrasound to differentiate cellulitis from non-infectious insect bite in 304 children. Both of these studies will recruit from emergency department populations, which are likely to be more selective than those consulting to primary care. However, they use technologies suitable for primary care and one appears well powered to evaluate diagnostic accuracy.

**What should we do in the light of the uncertainty?**

Given the current limitations in the evidence for the use of novel diagnostic approaches in primary care, clinical assessment is the mainstay of diagnosis. Box 2 lists criteria on history that increase the likelihood of cellulitis. On examination, recent overviews describe classic signs of cellulitis as acute unilateral erythema, pain, heat, swelling, and tenderness. There may be ascending lymphangitis and tenderness. The affected area may be well demarcated or diffuse.2

**Box 2: Clinical features that increase the likelihood of cellulitis**

**History**
- Previous cellulitis
- Lymphoedema/chronic leg oedema
- Excoriating skin diseases
- Tinea pedis or obvious site for infection to have penetrated through
- BMI >30

The observational studies identified suggest that, in differentiating cellulitis from other causes of red leg, a unilateral presentation greatly increases the odds of cellulitis. Bilateral cellulitis is uncommon but may complicate chronic dependent oedema or lymphoedema.

In unilaterally affected limbs, a lack of elevated temperature compared with an unaffected limb can help to rule out cellulitis. Consider alternative diagnoses (table 1), the approach supported by VCDSS, in particular, for patients with bilateral red legs and red legs that are not warmer than other body parts. However, given the ongoing uncertainty and risk of complications, antibiotic prescription is reasonable if in doubt. Consider referring patients with signs of systemic toxicity or uncontrolled comorbidities for hospitalisation. Identifying necrotising fasciitis requires a high index of suspicion as characteristic features may be absent initially (table 1) and emergency referral to hospital for investigation is indicated.

**Education into practice**
- What alternative diagnoses would you consider when a patient presents with a red leg?
- What factors would you consider when making a decision to start antibiotics in a patient presenting with red legs? How could you share the decision making around antibiotic prescribing with a patient where you are not confident in the diagnosis of cellulitis or stasis dermatitis?

**What patients need to know**
- Several conditions can cause red legs. One of these is a bacterial infection called cellulitis. Cellulitis should be treated with antibiotics to avoid potentially serious complications
- Emergency department studies have found that up to a third of patients seen with red legs are given antibiotics for cellulitis when they actually have another condition for which these are not the best treatment
- Four different kinds of tests have been evaluated to see if they can help doctors tell whether red legs are caused by cellulitis
- These new tests have been evaluated in only small studies, and no studies were conducted in primary care settings
- Before GPs could start using a new test, research would be needed to show that it was able to identify cellulitis accurately in patients seen in general practice, and to show that by using it patient outcomes were improved
How patients were involved in the creation of this article

We shared the research question and our findings with the NIHR Community Healthcare MedTech and IVD Cooperative’s “Appropriate antibiotic prescribing” patient and public involvement group. The group suggested that the focus should be on management outside hospital settings, and we incorporated this into our exclusion criteria. Group members advised that recommendations should take into account the likely discomfort or invasive nature of potential tests and their applicability to home monitoring of antibiotic response. We have included these elements in our discussion. We thank these patients for their input.

Competing interests

The BMJ has judged that there are no disqualifying financial links to commercial companies. The authors declare the following other interests: none.

**What to do when uncertain**

Clinical features that increase the likelihood of cellulitis:
- Previous cellulitis
- BMI >30
- Lymphoedema/chronic leg oedema
- Excoriating skin diseases
- Tinea pedis or obvious site for infection to have penetrated through

**Empire patient for**

- Acute unilateral erythema, pain, heat, swelling, and tenderness
- Can be associated with ascending lymphangitis and tender groin lymphadenopathy
- Affected area may be well demarcated or diffuse

**Unilateral redness**

- **Infective**
  - Acute necrotising soft tissue infection
  - Deep sub-acute/chronic infection
  - Septic arthritis/bursitis
  - Unusual pathogens

- **Non-infective**
  - Vascular disease
  - Crystal arthropathies

**Bilateral redness**

- **Infective**
  - Bilateral true cellulitis
  - Infected ulcers

- **Non-infective**
  - Vascular disease
  - Systemic inflammatory diseases
